particle of food or drink without choking. Every method known to intubationists was tried, but all failed. I therefore adopted the plan of removing the tube about 9 A.M., and replacing it at 6 P.M. This worked admirably, especially as the removal of the tube was much simplified by the use of the laryngoscope. The tumor could be seen to be diminishing in size daily. The boy was breathing easily, and eating well. Intubation was continued daily (except during two periods, of about three days each, when he went home for a visit) until August 7th. At this time the tumor had essentially disappeared from the cord, although there still remained a little growing from the surface in the anterior angle between the cords, where little or no pressure was exerted by the tube. To remove this growth, I had two little curette-like projections of gold plate soldered onto the tube, as shown in the cut. The use of the tube, as thus armed, for two days (making two withdrawals), sufficed to remove every vestige of the growth, and the case was dismissed.

The most noticeable effect of the first insertion of the tube, aside from the relief to respiration, was the change in the pulse-rate. For years the pulse had never been less than 120 per minute; it now dropped to 80, and remained there. The boy gained four pounds in weight while under treatment, and ten pounds during the next four weeks; an increase of nearly fifty per cent. September 5th he reported for examination. Vocalization was distinct, but harsh. No evidence on inspection of any return of the growth. At this date, November 30th, he is reported as strong and well, going to school, and talking as well as any boy of his age.

As this method of treating a case of this sort was to me novel, I wrote, August 3d, to Drs. O'Dwyer and Waxham, asking them for information. Dr. O'Dwyer replied that he had not before believed that enough pressure could thus be brought to bear to do any good. In a case of papilloma, in a child aged three years, he had left a tube in continuously for about ten days, without effect. Subsequently, he coated the head and neck of the tube with dried alum, by means of gelatine, and inserted it, recoating every third day. This he continued for two weeks, but without effect. He does not state what size tube he used.

Dr. Waxham replied that he had had but one case of papilloma which he had treated incidentally by intubation. "The case was that of a boy, aged two and a half years. I was not called until the danger from suffocation was imminent. I introduced the tube as a temporary measure, which was worn a week, and then patient did well without it for several weeks. The dyspnœa, however, returned. I then coated the tube with gelatine, and applied chromic acid, and then another coating of gelatine. Several applications of chromic acid were made in this manner. I then left for Europe, leaving the boy with the tube *in situ*. The physician in whose care I left him had some difficulty in extracting the tube, and performed tracheotomy and removed the tube. Upon my return I found him wearing the tracheotomy tube, and the larynx entirely closed by adhesions. Laryngotomy was performed, the adhesions broken up, and the remnants of the growth removed, and an intubation-tube introduced. He has now been wearing the tube over a year, and is still unable to breathe without it. The difficulty has been from the adhesions rather than from the growth."

It seems a pity, since the wearing of the tube for a week gave relief for "several weeks," that the effect of persistent use of the tube was not tried before resorting to the caustic.

I am unable to account for the persistent inability of my patient to swallow food without choking; out of about forty cases of intubation that I have had, this is the only one presenting that difficulty except temporarily.

August 28, 1889, Anna McN——, of Lafayette, O., aged nine years, was brought to my office, suffering from extreme dyspnœa, due to tuberculous growths in the larynx involving both cords, though mainly the left. Both lungs were also involved, and it was evident that she could live but a short time. Intubation relieved the dyspnœa at once. She coughed the tube out in four or five days, but her breathing remained easy, and on inspection the growths were found much reduced in size. She died in about six weeks, but the laryngeal obstruction did not return.

I wish to place these two cases on record, hoping that they may serve to broaden the field for intubation.

Note.—As ordinarily made, the shank of the obturator is stiff, with a single joint. While the expert intubationist finds no difficulty in withdrawing this obturator, the tyro will not infrequently find it to catch and cause delay. To obviate this difficulty, I some time ago had Shepard & Dudley make me a set of obturators, in which the stiff shanks were replaced by braided silver wire. I have found them a decided improvement.

The Morphine Habit is said to be constantly on the increase in this city, as well as elsewhere, a number of the victims being physicians. A corroboration of this report is found in the fact that a single firm in Portland, Me., has made and sold over four thousand needles for hypodermic syringes every year for the past six years. Other places, of course, make many more, and it is evident that they are not all used by physicians only. It has been proposed to restrict the sale of hypodermic syringes to practising physicians, but it is very doubtful whether such a measure would be of any use, as the law would be evaded just as that against the sale of poisonous drugs is now.

ON THE VALUE OF ABSOLUTE REST AND STARVATION IN THE EARLY STAGE OF TYPHOID FEVER.

By R. F. LICORISH, M.D.,

BRIDGETOWN, BARBADOES, WEST INDIES.

PROBABLY there are few physicians in the present day who recognize the possibility of aborting typhoid fever. Of the medicines and other means brought forward as having that end, none have stood the test of experience, hence any new method that may be proclaimed as having that claim will probably receive but little attention.

From these considerations I have hesitated long before putting this, my experience, before the profession. Having, however, decided that to get at the truth of anything it is best to put it to the text of many experimenters, I offer it through these pages with the hope that those who follow its suggestions may get the same results as the writer.

For the past six years I have adopted a plan of treatment in typhoid fever having for its chief objects the re-establishing of the appetite and the retaining of the heart's strength; objects which, in the treatment of all acute diseases, are of the first importance.

In the treatment of typhoid our aim should be: 1, Maintaining the heart's strength; 2, re-establishing the appetite; 3, maintaining mental quietude; 4, providing thorough ventilation.

The last two of these appeal so to everyone as to render it useless to say anything further about them. The first two, although equally recognized as of the utmost importance by all, are yet more difficult in carrying out; hence, any method by which they may be attained certainly deserves attention. In order, then, to maintain the strength of the heart, I rely on absolute rest in the horizontal position; and the earlier this is resorted to the better will be the results. I make it a practice to enforce on the patient, at my first visit, the importance of at once assuming that position, and also of maintaining it faithfully until the crisis has passed and convalescence is well established. He must not on any account rise even to the semi recumbent position. To avoid rising to take food and medicine, and going to stool, a bedpan and feeding-cup are brought into use at once. Even the exertion of changing clothes is not allowed until all danger of doing so is past.

The importance of this absolute rest is soon shown on the heart, which maintains its strength and regularity to a surprising degree.

To restore the appetite, I instruct the nurse not to give the patient any nourishment until he calls for it; but to give water whenever required. Sometimes about four ounces of milk is allowed daily until the appetite returns, which is usually about the fourth to the sixth day. Thus, to starve a patient suffering from a disease, the most frequent cause of death from which is heart-failure, must, to some, appear almost criminal. We must remember, however, that this treatment is only recommended in the early stage, *i.e.*, before the heart has become weakened by the fever; and also that the treatment is only carried out in those who maintain the horizontal position—the best heart tonic. Moreover, in the early stage of typhoid fever, as well as in all other acute diseases, the digestive tract is in a state of catarrhal congestion—a condition, we have every reason to believe, which not only lessens, but also vitiates the digestive secretions, hence but little nourishment can be assimilated.

The result of this treatment is soon apparent. The patient, from being thus deprived of food, after a few days says he feels hungry, or expresses a wish for certain articles of food. His appetite is returning! When this is gained the battle is half won; for convalescence is soon established. By starvation the stomach gets rest—no food being introduced which it is unable to digest—all effete material is carried off, the catarrhal condition is reduced, the appetite is regained, and with these the temperature, showing no inclination to ascend, either remains stationary for a few days, or shows a decline at once.

After the appetite is thus regained the utmost care should be exercised in giving nourishment, which must be very gradually increased, for if the appetite be again lost the temperature rises and other symptoms appear. When seen early and thus treated, it is the rule for a normal temperature to appear from the tenth to the fourteenth day, or even as early as the eighth, when treatment is begun as early as the first or second day of the fever.

At first it was a matter of doubt to me that typhoid fever could be so modified and aborted; but I have so frequently seen it occur in the treatment of over six hundred cases as to leave no doubt whatever on my mind.

Of course the question naturally arises. Were such cases true typhoid fever? If unable to answer this question in the affirmative, the following reason, however, enables me to answer in the affirmative one of equal importance. Can typhoid fever be aborted? It is this: I have again and again seen cases so treated and aborted pass through marked typhoid relapses from neglecting those precautions necessary to prevent them.

Conspicuous, too, in these aborted cases is the absence of tympanites and diarrhœa, except in rare cases; thus proving that those two conditions are largely, if not solely, due to over-feeding.

Typhoid relapses are, in almost every case, due to one or more of the following causes: 1. Too early physical exertion, as sitting up in bed, etc. 2. Too early resort to solid food, or to over-feeding. 3. Mental excitement.

That cases of this fever are protracted to five, six, or even seven weeks, certainly shows a fault in their management somewhere; usually either on the part of the physician or that of the nurse. There are cases, however, in which all the blame lies on the patient himself, and this is seen most frequently in his sitting up before being allowed to do so; hence the physician should take the trouble of reiterating his injunctions frequently.

That physicians do not in all cases recognize the danger of allowing patients to sit up in bed is seen in the number of cases in which they are allowed to sit up in the second and even in the third week of the fever, and not until the appearance of heart-failure is the horizontal position strictly enjoined. Now, as "prevention is better than cure," would it not be wiser to enforce that position in the earliest stage? thereby preventing heart-failure or its appearance?

The general practitioner certainly has a great advantage in seeing disease in its beginning, and the great aim should be to "nip it in the bud." As a rule, however, we get little credit for checking a disease in its first stage; whereas we get applause when we pull a patient through a severe case. If, however, the patient dies in spite of our efforts, Providence is saddled—often, however, with the fruit of our carelessness or ignorance.

I am very glad to see that Mr. Lawson Tait recognizes the value of starvation, in not allowing nourishment to those operated on for nearly forty-eight hours after the operation. This is surely one reason for his great success as an operator.

The following conclusions may then be deducted from the preceding statements: 1. That typhoid fever may be aborted. 2. That to be so aborted the patient must be seen and treatment begun within the first few days of its onset—initial chill. 3. That our chief aim should be to restore the appetite, so that the patient may be nourished and rendered able to throw off the disease. 4. That to create an appetite the patient should be deprived of food until nature demands it; or if any be given, only in very small quantities at a time. 5. That the maintenance of the horizontal position so retards or prevents heart-weakness as to enable us to starve the patient without any risk. 6. That great care should be taken in feeding the patient after he has regained his appetite; for should it be again lost the temperature rises and a relapse occurs.

I must here state an important point in the treatment,

omitted above. It is this: After a normal temperature has been gained, at least one week should elapse before the patient be allowed to sit up, and at least ten days before solid food be given, and then only in very small quantities at a time. By attending to these precautions relapses are prevented, and the patient never in any danger. Of course I give medicine to meet symptoms as they arise; but as I was never able to abort cases before adopting the above treatment, I of course conclude that rest and starvation are the agents to which the results are due.

This treatment, thus shown to be so efficacious in typhoid fever, I have put into practice in other acute diseases with equally satisfactory results, although in those diseases the same data for drawing conclusions are not present as in a disease running a definite course, as typhoid fever.

Given the means whereby the patient may be starved without risk, may we not also treat successfully many chronic local congestions and inflammations, bringing to our aid, after the removal of the congested condition, such means as massage and feeding to complete the cure? May not such diseases as cirrhosis of the liver and pelvic congestions, etc., be amenable thereto? My experience in this class of diseases is so limited as to allow me only to throw out the hint, leaving to others, who have the courage, to carry out the suggestions.

December 14, 1889.

Clinical Department.

A CASE OF RELAPSING APPENDICITIS—REMOVAL OF APPENDIX—RECOVERY.

By B. E. HADRA, M.D.,

PROFESSOR OF SURGERY, TEXAS MEDICAL COLLEGE.

The history of the following case is not published with the intention of settling the question whether appendicitis (perityphlitis) should receive surgical treatment or not, and under what conditions. My object is to add another to the small number of cases of relapsing appendicitis which have been subjected to operative interference, not prompted by necessity, but rather with the view of preventing dangerous consequences. Since Treves' classical researches and the publication of his first operation (*Medico-Chirurgical Trans.*, 1888), to my knowledge, only three such operations have been performed—one by Treves and Swallow (*Lancet*, 1889), one by Senn, and one by Hoegh (both reported in the *Journal of the American Medical Association*, November, 1889). All the cases terminated favorably. Being one of the safest and simplest of abdominal operations, it only takes more practical experience to place it among the list of the recognized and generally accepted procedures. There is, of course, a vast difference between an operation when there is active inflammation, abscess, perhaps perforation and peritonitis, and such cases where there is, at the most, a chronic irritation or a very slight chronic inflammation, or some malposition, twisting, or any other abnormality, at the bottom of the trouble.

Case.—A sturdy German baker, aged fifty-two, was taken with constipation and colics about six months before operation, which was performed on October 6, 1889. He could assign no cause for it. The usual treatment—attempts at evacuation of bowels by enemata and opiates—relieved him promptly. Three or four similar attacks were checked by the same means. They occurred at intervals of one to two weeks. There never was much difficulty in moving the bowels. Gradually the intervals became shorter, so that two attacks occurred in the same week. He became accustomed to treat and relieve himself by morphia and rectal injections. I saw him first, in a more severe attack, about six weeks previous to the operation. The cæcal region was then resistant to the touch, but no distinct tumor could be felt. At a second visit, eight days before operation, the same condition existed, but there was a spot, the size of a silver half-dollar, about two inches inside of the anterior superior spine of the ilium, which was extremely tender and which was insisted on as the site of the pain in every attack, and of a dull neuralgic sensation at other times. The patient, claiming to be perfectly invalided, insisted upon an operation, at which I had hinted.

On October 6th, after the usual preparations, and just after an attack had faded away, with the assistance of my colleagues, Drs. Dock, Sykes, and West, the following operation was performed. The usual crescentic incision, the convexity to the right, of about six inches, was made over the cæcum, so as to make the painful point the centre. On opening the healthy peritoneum the tip of the appendix presented at once. The latter was about two inches long, thicker than a common pencil, had a complete mesentery, and was nowhere adherent. Its peritoneum seemed slightly cloudy. Altogether it would at the first glance have passed as a healthy organ. The cæcum showed no alteration at all. Thus, though the appendix appeared not particularly diseased, its abnormal position—in front of, and nearly across the end of the cæcum—and its location corresponding exactly to the seat of the pain, caused me to proceed, nevertheless, to its removal. It was tied close to the cæcum and cut off. The cavity of the stump, containing some fecal matter, was well rubbed with iodoformed cotton, and closed by three Lembert sutures.

All other steps were those usual in laparotomy. Everything went on smoothly except that the skin-wound, from some unknown cause, did not heal by first intention. The pain and tenderness disappeared, and have not returned to this date, nearly four months after the operation.

Pathological Report by Dr. George Dock.—"The appendix as removed was not quite two inches in length and about three-eighths of an inch in diameter, being wider than the average. Externally it showed no alteration, except slight cloudiness of the peritoneum. It contained a small quantity of thin, yellow, feculent matter. On cutting it up along the mesentery several dark reddish, slightly elevated spots appeared in the mucous membrane. They were round or oval, and from a quarter to half an inch in greatest diameter. There appeared to be no breach in the continuity of the mucous membrane. The specimen was placed at once in strong alcohol and hardened. Sections were cut later, and stained with hæmatoxylin and eosin, and with Loeffler's alkaline methylen-blue. All these show to a greater or less extent the following: The surface epithelium is intact, the tubular glands unaltered. Below and above the lymphatic nodules, and to a less extent in the intertubular tissue, are hemorrhages, the extravasated blood lying in foci the size of a pin's head, or intimately mixed with the elements of the tissues. The veins of the submucosa are all dilated and filled with blood, the arteries, almost without exception, empty. The lymph-nodules show no other alteration, but there is a slight general increase of small round cells near them and in the neighborhood of the blood-vessels of the submucosa. The muscular coat shows no alteration. The serosa, compared with that of other specimens, is slightly thickened. The changes here, aside from the hemorrhage, are so slight as scarcely to deserve mention.

"The total absence of pigment masses and the general appearance of the effused blood shows the hemorrhage to have been of recent occurrence, and in the absence of other signs of active inflammation I am disposed to look on it as passive, caused by the ligature. (It may be well to add that the blood-vessel walls show no alteration, nor are there any bacteria in the tissues.) I look on the specimen as an example of chronic catarrhal appendicitis of mild grade."

I think I am justified in claiming a cure by the operation, as perfect relief has been obtained from the moment

the appendix was removed. The question, though, arises, What was the cause of the trouble? Was it the slight catarrhal alteration of the mucous membrane, or the still slighter irritation of the serosa? or was it rather the unusual position—perhaps, also, a temporary twisting only of the appendix—with consequent circulatory disturbances? Not being able to decide positively, I am inclined to adopt the latter explanation, in view of the report by a perfectly competent pathological anatomist. It is difficult to understand how an inflammation of the appendix, serious enough to cause such distressing symptoms, could disappear in two or three days and leave hardly a trace behind. On the other hand, it may be assumed that the appendix, always or temporarily holding this unusual relation, may have brought on a kind of strangulation of the cæcum, whenever the latter accidentally became overdistended. This is, of course, speculation, but it may go to show how manifold may be the first causes of perityphlitis (appendicitis). Treves' contributions, already alluded to, threw valuable light on these obscure ailments, and we should follow his advice, and operate wherever the trouble assumes a relapsing form. I would add the proposition to do so, if possible, in a free interval, as we may then expect the least inflammatory complications and the least reaction.

WHERE DID THE BULLET GO?

By C. B. WOOD, M.D.,

HONOLULU, H. I.

The following case is reported by way of caution in this day of bold operative surgery, and to emphasize the importance of Dr. Senn's hydrogen test in cases of gunshot wounds of the abdomen.

The patient, Chun Tai Choy, a Chinaman, twenty-one years of age, was brought into the Queen's Hospital at 8 o'clock P.M., on October 11, 1889, suffering from a perforating pistol-shot wound of the abdomen.

The following is the history obtained from his friends: On October 9th, at about 8 P.M., or forty-eight hours before his admission to the hospital, the patient, while in the act of urinating, was shot from behind by another Chinaman with a revolver of probably 32 calibre. This occurred in the country, about thirteen or fourteen miles from Honolulu. On the morning of October 11th they started for town with him, being obliged to cross a mountain pass over twelve hundred feet high on the way. He was brought to the foot of the pass in a brake, carried to the top, and brought the rest of the way in a carriage, reaching the hospital as before stated, at about 8 P.M. When admitted to the hospital he was in excellent condition, notwithstanding the long and hard journey. There were no signs whatever of collapse. His pulse was good and not over 80. Temperature not over 101° F. The only pain complained of was in the left thigh and leg. There was very little tenderness over the abdomen.

On examination the wound of entrance was found to be at about the junction of the last dorsal with the first lumbar vertebra, the inner edge of the wound being just ¼-inch to the right of the median line of the back.

A tape-line carried around the body on a level with the wound crossed the linea alba at a point midway between the ensiform cartilage and the umbilicus. The direction of the wound was downward and forward. The wound of exit was one inch above the pubic arch, directly in the linea alba. It seemed impossible that a ball could have passed through the body in the course that this one had apparently passed without perforating the intestines. But the man's whole condition was so good that an operation was out of the question, considering that forty-eight hours had already elapsed since the injury.

For the same reasons Dr. Senn's test with hydrogen gas was not made use of. Antiseptic dressings were applied and an hypodermatic injection of morphine (¼ gr.), and atropine ($\frac{1}{150}$ gr.) administered. The subsequent treatment consisted in keeping the bowels confined with opium for the next five days, during which time a liquid diet only was allowed. At the end of this time an enema was given and the bowels emptied. No bad symptoms followed. The range of temperature was as follows:

October	12th,	A.M.	Temperature	101.4.	P.M. 102
"	13th,	"	"	100.4.	" 103
"	14th,	"	"	100.6.	" 101.4
"	15th,	"	"	99.6.	" 100

After the 15th the temperature was normal. The patient had no bad symptoms at any time, and the only pain complained of was in the left leg and thigh. On the 16th or 17th he got out of bed and walked, and now (21st) is on ordinary diet. Of course the bullet did not perforate the intestines, but it is hard to understand *why* it did not.

HERNIA CEREBRI.

Dr. C. E. Olmsted, of Syracuse, N. Y., writes that when he was one of the visiting physicians of the Board of Health in this city, he saw a peculiar case of protrusion of brain-substance through the frontal bone. The tumor was congenital, the child at the time he came under Dr. Olmsted's notice being five years of age. The opening in the frontal bone was about the size of a silver dollar. The pulsations in the tumor could be distinctly seen as well as felt. The child had convulsions at irregular intervals, coming on apparently without any special exciting cause. At these times the brain-substance would recede through the opening in the skull, and then the defect in the frontal bone could be readily defined by the finger. Upon the cessation of the convulsions the tumor would again become apparent, forming a projection on the forehead about the size of a plum.

DILATING URETHROTOMY.

Dr. H. W. Streeter, of Rochester, N. Y., writes: "I believe the importance of dilating urethrotomy is not sufficiently appreciated by the profession at large, although a vast literature on the subject has accumulated during the last fifteen years. For the purpose of assisting to popularize one of the most useful operations in all surgery, I submit the following report of a year's work. I have operated in cases of gleet, 129 times, spermatorrhœa, 54, impotence, 38, premature emissions, 23, irritable bladder, 6, sciatica, 2. One of the latter was cured, and one not benefited. Four of the cases of irritable bladder were cured, one improved, one unrelieved. In fully ninety-five per cent. of the other cases the results have been eminently satisfactory. Most of these cases were of old standing, and had been treated in the usual way by internal medication, injections, or electricity. In view of this there can be no doubt that the results were due to the operation. To those who are inexperienced in dilating urethrotomy and prejudiced against it, I would say 'try it.' No man was ever converted to belief in the reflex influence of genital irritations, especially of stricture, against stronger prejudices than the writer."

The Origin of Fever.—M. Roussy, in a paper read before the Academy of Medicine by M. Schutzemberger, states that fever is often the result of soluble non-organic principles, but of microbian origin, being introduced into the animal economy. He has ascertained that injecting into the blood or under the skin water in which different organic matter has been macerated also determines a febrile condition. M. Roussy has isolated the pyrexogenic element, and concludes from the results of his experiments that certain diastasis or zymosis (soluble ferments) have a febrile influence; the water in which the yeast of beer has been macerated is an instance. M. Roussy used the same method as M. Berthelot for obtaining "invertine," and it is possible that the body discovered by M. Roussy is identical with invertine.—*The British Medical Journal.*

Progress of Medical Science.

Absolute Milk Diet in Cardiac Disease.—A critical paper on the value of absolute milk diet in heart disease has been published by H. Högerstedt. Urged by the objection brought forward by F. A. Hoffmann in his discussions upon total milk diet, that there are no reliable recorded histories where the milk regimen has been pursued in a strictly scientific manner, the writer describes fully a carefully followed-out case, from the Dorpat clinic, of pure mitral stenosis, in which Karell's total milk regimen was repeatedly followed with excellent results. From the circumstance that pure mitral stenosis, where there is commencing failure of compensation, opposes the utmost difficulties to therapeutic treatment by the ordinary cardiac remedies, the author believes that he had a peculiarly favorable opportunity of judging of the influence of pure milk diet upon the action of the heart. The case observed was in an advanced degree of failure of compensation. Digitalis, tried after complete failure with calomel, was of no service; caffeine also had no effect; there was no tonic action upon the heart; and the state of the patient was extremely serious from the general venous congestion and weakness. On the contrary, the result with total milk diet, after six months' observation, twice repeated, was most striking. The highly favorable action on diuresis and pulse became evident as early as the fourth and fifth day after the commencement of exclusive milk diet; and at the same time there supervened a remarkable diminution of congestion and a general improvement in the condition of the patient. From experiments made under different dietetic conditions the author was able to draw up the following table:

	Diuresis.	Albuminuria.	Pulse frequency.	Coogestion.	General condition.
Absolute milk diet.	Rapidly increases and remains great.	Rapidly diminishes and disappears.	Becomes less until it reaches and falls below normal.	Diminishes and disappears.	Improves surprisingly.
Milk diet principally	Gradually falls.	Steadily increases.	Very gradually increases.	Very slowly increases.	Gradually gets worse.
Full diet.	Very slight.	Remains constant.	Remains high.	Reaches a high degree.	Bad.

It is important to insist upon gradual increase of the amount of milk taken, and to give it in small quantities (Weir-Mitchell). As regards the difficulties to be encountered in the carrying out of repeated cases of the milk regimen, the practitioner must not yield but continue firm. Though according to Hoffmann's experiments under other conditions an absolute milk diet is undoubtedly hunger diet, yet in the case of the sick kept from working and needless loss of heat, as among children, it may become a growing diet. Indeed, we possess in total milk diet, in so far as pathological and anatomical conditions do not prescribe limits to us, a remedy for failure of compensation in cardiac disease which can favorably influence the power of the heart and the blood formation, even when reliance upon every medicament must be altogether doubtful.—*The Practitioner.*

European Infantile Mortality.—A comparative study of infant mortality in different European countries has been made by Dr. Fodar, with the following results: Of 1,000 children born alive, 106.3 die during the first year in Norway, 137.1 in Sweden, 154 in England, 169.1 in France, 217.7 in Prussia, 220.1 in Italy, 254 in Hungary, 258.2 in Austria, 317.1 in Bavaria, and 329.5 in Würtemburg. With regard to Bavaria, there is considerable difference in the infant death-rate in different districts. Thus in Suabia it reaches the enormous figure of 409 (nearly four times as great as that of Norway), and in Upper Bavaria it is 406, while in the Bavarian palatinate it is only 187. From these statistics it would appear that the hygiene of infancy is better understood in Norway than elsewhere, and that German nurslings are either particularly delicate or particularly unfortunate in the mode of their bringing up.—*Deutsche Medicinische Wochenschrift.*

Total Extirpation of the Patella.—Dr. E. Kummer, of Geneva, has published a contribution on this subject, in which he advocates the following propositions: 1. Total extirpation of the patella can be performed without impairing the patient's gait or markedly interfering with movements of the knee-joint. 2. The operation is indicated in cases of tubercular osteitis of the patella, provided the articulation remains yet intact. 3. The extirpation can actually prevent the development of articular lesions and thus save the knee-joint, provided the operation is resorted to sufficiently early. 4. In cases of tubercular osteitis of the kneep-cap a total removal of the bone offers better chances in regard to recovery than scraping out the morbid foci (*évidement*). Hence, as a rule, the former operation should be preferred to the latter. Dr. Kummer adduces an illustrative case, referring to a girl, aged twenty-five, with primary tuberculosis of the right patella, but with a perfectly intact knee-joint, where he made excision of the bone, and that with excellent results. When shown to the Société Médicale de Genève, about two months after the operation, the patient was able to extend her right lower limb as under normal conditions; would kneel with perfect freedom, and without any pain or discomfort; could walk four or five hours daily without lameness or fatigue, or run up and down staircases with ease, etc. In short, the only inconvenience caused by the absence of the knee-cap consisted in a relatively weakened extension of the corresponding limb. A similarly successful case of total removal of the patella has been published by Professor Kaufmann, of Zurich. in the *Correspondenz Blatt für Schweizer Aerzte.* The patient, a married lady, aged thirty-three, was suffering from fungoid osteitis of the left knee-cap, of eight years' standing. The operation was performed in November, 1882. A month later the lady, being frightened by a fire next door, tore off all dressings and ran out of her house, having swiftly descended a staircase. "Since then her knee-joint remained perfectly movable, her gait normal." Dr. Kummer mentions further two cases of primary tubercular osteitis of the patella (in boys of ten and seventeen) in which the whole of the bone was removed by Professor Th. Kocher, of Berne. In both, however, the knee-joint did not recover its movements (in one the articulation had been already partially destroyed by fibroid anchylosis, and remained anchylosed in spite of the operation; in the other the extirpation was resorted to rather late. An interesting case of total excision of the patella for acute necrosis has also been published in *The Lancet*, March 16, 1889, by Mr. Page, of Newcastle-on-Tyne. The patient recovered with a perfectly useful limb.—*The Provincial Medical Journal*, January, 1890.

Paralysis from Arrest.—Professor Eulenburg has recently reported a case of the above kind of paralysis following arrest. In 1882 Bernhardt first drew attention to the fact that grasping of the arm, as performed by police officers in the act of arrest, over the part where the radial nerve comes to the front, was followed sometimes by paralysis of the hand. He reported some cases. Bernhardt in consequence of his observations made the suggestion that officers should grasp their charges immediately above the wrist. Professor Eulenburg's case shows that even grasping in this locality can be followed by evil consequences if the force used is sufficiently energetic. During a short walk of not more than three hundred yards, the median nerve, in this case, suffered sufficient compression to produce paresis, implicating both sensory and motor functions.—Berlin Correspondent of the *Medical Press and Circular.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, March 8, 1890.

THE MEDICAL SERVICE IN THE MERCHANT MARINE.

IT is strange that so little attention should be paid to the medical service on passenger ships when everything else that can in any way contribute to the comfort and safety of those who cross the ocean is made the subject of most careful study. The navigating officers, the engineers, and even the seamen are selected with care, and it is very seldom that one who is not known to be competent is accepted by any of the steamship companies. Yet when it comes to the selection of the officer to whom the health of the passengers and the hygienic management of the vessel is, or ought to be, confided, no care whatever is taken in the majority of instances to exclude those who may be utterly incompetent. The companies seem to regard it as an imposition that they should be compelled to provide a physician, and they take any man that comes along and can get a recommendation from some friend of the management. An amusing illustration of the indifference with which the companies, and the public as well, regard this important matter was shown not long ago in the case of two rival lines sailing from this port to the South. The vessels of one of the lines carried physicians, and so stated in their announcements. The other company thereupon advertised that they did *not* provide surgeons, and as they lost nothing by this course in the way of passenger traffic, the other company dismissed their surgeons and pocketed the small salary that they had paid them.

There are, of course, some good men in the employ of steamship companies, but they are unfortunately in the minority, and it is safe to say that a large number of ship's-surgeons would with difficulty be able to hold their own in competition with their confrères on land. The blame for this state of affairs rests—where shall we say? With the companies or with the travelling public? Of course the companies are at fault in not having the best men that could be found for the service, yet they can hardly be blamed so much for not going to the expense of providing high-priced surgeons when the patrons of the lines do not demand it. The average pay of a ship's surgeon is $50 per month, a sum that would tempt only a very young man, one who had failed on shore, or one whose love of the water or whose health drove him to a seafaring life. Of the latter there are not a few, yet the former class, we fear, will contain the majority. If a larger salary were paid, and a closer scrutiny were made into the qualifications of the surgeons, it would not be difficult to bring the service up to any reasonable standard of excellence. But that would take money, and in these days of active competition the steamship companies have little money to spend in what they consider useless luxury.

There is little hope, then, of an improvement in the medical service on ocean steamships until the travelling public realizes how its interests are neglected in this respect and until it demands of the steamship companies a reasonable amount of care in the selection of the medical men to whom are intrusted the lives of the passengers.

EVERY MAN WITH HIS OWN DISPENSARY.

IN a recent article in these columns upon the dispensary abuse we suggested that each man might have a dispensary of his own if he were so disposed, giving a part of certain days or of each day to the poor. We are glad to learn that this suggestion has already been acted upon by one gentleman at least, and we hope that he is only the pioneer in a reform that will undoubtedly benefit in no small degree the younger practitioners in this city or in any city in which the custom may be adopted. This gentleman has had cards printed after the model of the regular dispensary card, stating that he will give free consultations to the poor from nine to ten o'clock every morning. The card also contains the announcement that a certain druggist in the neighborhood will put up prescriptions at half price.

The doctor has been accused by some of his brethren of unprofessional conduct in publishing the fact that he will treat the deserving poor gratuitously, but we must confess that we fail to see wherein the unprofessional conduct lies. It would have been better, we think, had the apothecary's name not appeared upon the doctor's dispensary card, but that is perhaps a matter of taste rather than of principle. As for printing and distributing the cards, there is no crime in that, or if there is, there are many criminals in this good city of New York. The dispensaries distribute cards with the names of the attending physician upon them, and some of them did, not long ago, and may now for all we have heard to the contrary, advertise in the daily papers, giving not only the names of the attending physicians but also their addresses. If a corporation of physicians can publicly advertise, why should a private individual be debarred from letting it be known quietly that he is ready to run an opposition to the corporations in caring for God's poor. His right to give his services can certainly not be questioned, and it is our opinion that there is nothing unprofessional in systematising his charitable work by appointing stated hours and by giving cards to his free patients. His dispensary has as much right to exist as any other, and methods that are legitimate for a public dispensary are also proper for a private one.

The dispensary evil is a real one, it is taking the means of livelihood away from many deserving young men, it is growing constantly, and it must be combated to be kept within proper bounds. The remedy that we have suggested seems to us to be the only effectual one. We congratulate our friend who has had the courage to oppose

the evil by starting a dispensary of his own, and we should be glad to see the example that he has set followed by other physicians throughout this city. An attempt was made some time ago to organize concerted opposition to the dispensary abuse, but for some reason the movement never came to anything, and there is nothing left but for each individual to act for himself.

THE MEDICAL PROFESSION AND THE WORLD'S FAIR.

The World's Fair, if there is to be one, will be held in Chicago in 1892 or 1893. We have already called attention to the fact that American medicine and surgery should be represented, and represented well on this occasion. It will not be necessary to attempt to hold a large series of International Congresses, as was done in Paris. We doubt very much if this could be done very successfully. Even at Paris these Congresses were not, as a rule, very notable gatherings, and were made up mainly of the French.

It would be possible, however, for the profession of the three Americas to make some most interesting exhibits, and to have some very instructive conferences.

Illustrations of the development of medical, surgical, and sanitary science, and of hospital construction, should be made, and the occasion might well be taken to bring into closer relations with us the medical fraternity of Central and South America.

For these various purposes a good organization and plenty of money will be needed. Probably the machinery of the American Medical Association will be employed in carrying out the plans. This Association has always made Chicago its centre, and although a good deal of criticism has been passed upon its efficiency and methods of work, yet the organization can be made no doubt to rise to the coming emergency.

We have no doubt that our Chicago brethren will be heard from when the proper time comes.

THE HISTORY OF MODERN MEDICINE IN JAPAN.

Dr. S. Nagayo, Director of the Sanitary Bureau in Tokio, recently delivered a very interesting address before the medical society of that city, in which he gave a history of the introduction and growth of Western ideas of medical practice in Japan (*Sei-I-Kwai Medical Journal*, December, 1889). Although some Spanish physicians appeared in Japan over three hundred years ago and instructed some of the natives in the healing art as it was practised in Europe at that day, yet when the persecution of the Christians began what little knowledge had been acquired speedily became traditional merely and was practically lost. About the year 1750 a native of Japan, Dr. Rankwa Maeno, became interested in the methods employed by the foreign physicians in the treaty ports, and learned the Dutch language in order to study the books in which this knowledge was contained. It is he that may justly be called the father of Western medicine in the East. He soon gathered around him a number of men who were eager in their study of Dutch, and employed their knowledge of the language in translating all the books on medical topics that they could procure. As an illustration of the perseverance of these pioneers in this branch of study it is said that they were able to translate only one or two lines of a medical book in an evening, yet such was their diligence that ten large volumes of translations were published within a few years.

The first modern hospital was established about thirty years ago, and with it was begun a school where both didactic and clinical instruction was given. The leaders in this were Drs. Pompey, a Dutchman, and Matsumoto, a native. Instruction was given continuously in this school, but it was difficult to get students to attend with regularity, many of them coming for short periods only, and apparently with the design merely of copying some of the prescriptions rather than of grounding themselves in the science of medicine.

It was not until after the revolution, in 1868, that medicine began to make any real and satisfactory advance, but when once it started fairly its progress was most satisfactory. At this time the military hospital at Yokohama was removed to Tokio, and the medical school was established there, many of the teachers being foreigners. A few years later the course of studies was graded, and the beginning was made of the medical department of the university. From this time the progress of modern medicine in the country was very rapid, the number of students increasing from year to year, and the proportion of physicians who practised according to the new methods becoming constantly greater. So striking, indeed, is this marvellous progress that we may well pardon the little conceit with which Dr. Nagayo closes his address, when he predicts that it is reserved for the physicians in Japan to unravel the truths of creation, and open to the world the gate of this great mystery.

THE MONUMENT TO DR. J. MARION SIMS.

It will please the many subscribers to the J. Marion Sims Fund to learn that the committee having the subject of a suitable monument in charge have given unceasing attention to the subject ever since the money to be appropriated in this way was so promptly and cheerfully contributed by the many friends and admirers of the late Dr. Sims. Endeavors were made to place the execution of the work in this country, and to this end a considerable number of models were submitted to the committee for approval by the Profession, and were exhibited in the parlors of the Academy of Medicine in this city. None of them, however, gave sufficient satisfaction to warrant the committee in an acceptance, and they were again obliged to seek for further propositions from sculptors, and this time they invited proposals from abroad. The design for a full-length figure, to be cast in bronze, nine feet in height, submitted by the Koniglischer Ergiesserei, of Munich, Bavaria (the most celebrated bronze foundry in the world), has given general satisfaction to the committee and to the members of the family of the late Dr. Sims who have seen it. The contract for its execution has therefore been awarded to Mr. Von Miller, the proprietor of the foundry. A recent letter from him states that they are proceeding with its execution. It is expected that it will arrive in America some time next year, accompanied by the design and working-plans for a granite pedestal of about eight feet in height. The question of its site in the Central Park

of this city, as first proposed, will, therefore, soon arise for consideration. It is proper for us to state further that the money contributed for this purpose has been, since its collection, deposited and still remains at interest with the United States Trust Company of this city.

News of the Week.

Dr. Caspar Barstow, of East Hartford, Conn., died in that town on February 22d. The cause of his death was pneumonia, following influenza. Dr. Barstow was thirty-five years of age, and was graduated from the University of Vermont in 1878. He began the practice of medicine in Windham County, Conn., and settled in East Hartford about five years ago.

A Woman's Medical College has been established at Atlanta, Ga., and the first Commencement was held on February 21st, the graduating class numbering one.

The Dispensary Abuse in Baltimore.—New York is not the only city that suffers from this evil, and now the physicians of Baltimore are complaining of the inroads made upon their practice by the dispensaries. The Johns Hopkins Hospital Dispensary is especially obnoxious to the medical residents in the northeastern part of the city, and it is charged that no discrimination is made against well-to-do patients, a large number of these received and treated being amply able to pay good fees for medical attendance were they compelled to do so. The dentists of the city are also beginning to find fault with the dispensaries on account of the looseness with which they dispense their charity, and a meeting of practising dentists was held recently to protest against the abuse, and to take measures for its correction.

Medical Legislation for Washington.—At the request, it is said, of the Medical Society of the District of Columbia, Senator Ingalls has presented a bill making it the duty of every physician in the District of Columbia to report to the Health Officer immediately he becomes aware of the existence of any case of scarlet fever or of diphtheria in his charge, and if such person shall fail to so report within twenty-four hours, he shall be subject to a penalty of not less than, or more than, twenty dollars, or in lieu thereof, shall suffer imprisonment for not less than one or more than three days. The bill also directs the Health Officer to cause a placard, flag, or warning sign to be displayed on the premises on which the patient is confined. The District Society should have seen that the bill contained a clause giving due compensation in money to the physician for the extra labor and expense it imposes upon him.

A Pneumatoscope.—The cable brings news of the invention of a wonderful instrument in Berlin, by means of which an exact differential diagnosis of diseases of the lungs will be possible. The inventor is Dr. Janiczewski. The description of the instrument is too indefinite to permit of an understanding of its *modus operandi*.

St. Peter's Hospital in Albany has issued its annual report, in which it is shown that there was increased work done during the year, and at a decreased outlay. The number of patients treated during the year was nearly six hundred.

Increased Death-rate in Maine.—In common with al other places Maine was visited by the influenza in January and February, and as a result the death-rate for those two months was greatly in excess of that for the same months in preceding years.

Dr. James Henry Budd, of Geneva, N. Y., was found dead in his bed on the morning of February 25th. Heart trouble is supposed to have been the cause of death. Dr. Budd was forty-four years old, and was graduated from the Buffalo Medical College in 1875.

Dr. Frederick L. Burden died of apoplexy in North Attleboro, Mass., on February 23d. Dr. Burden was born in East Douglass, Mass., in April, 1847. He enlisted in the federal army in 1861, serving during nearly the entire war. He graduated from Harvard Medical School at the age of twenty-one, soon after locating at North Attleboro, Mass. He was a member of the school committee of Attleboro, and was also medical examiner for a number of years. In 1882 he was elected to the State Senate, serving two years. In 1886, 1887, and 1888, he was Chairman of the Republican State Committee. He was a delegate to the last national convention at Chicago, and was one of the prominent candidates for the Collectorship of Boston.

Measles is Epidemic in some towns in Indiana. In Harrodsburg, a place with a population of only about five hundred, there have been one hundred and seventy-five cases.

Dr. Charles H. Miller, formerly of Lykens, Pa., was recently found dead in a freight car in Pittsburg. He was the son of a once prosperous mine-owner, who was ruined, and died in want. Dr. Miller was a physician, but had given more attention to writing than to the practice of his profession. He had a good theoretical knowledge of medicine, but was lacking in energy and other personal characteristics which are almost as necessary for success in practice as is a good education. He was, nevertheless, obliged to turn to medicine for a livelihood, and drifted about from one place to another in unavailing efforts to find enough patients to make a living. Finally, he decided to go West and settle in Kansas. There bad luck followed him. A short time before his body was found in the car in the Pittsburg yards, he wrote to a friend in Lykens that he would starve if he remained in the West, and was determined to work his way East. It is supposed that he was locked in a freight car, in which he was trying to steal a ride, and that he died there from starvation and hardship."

Another Dispensary.—A company with a capital stock of $50,000 has been incorporated in Chicago, its object being "to prescribe medicines and send them to sick people."

Dr. Charles W. Stevens, of St. Louis, died in that city on February 17th, of pneumonia, following influenza. He was born in 1817, in New York State, and had been in practice in St. Louis, with several interruptions, since his graduation in 1842. He was at one time superintendent of the St. Louis County Insane Asylum.

They Want a Doctor.—Eastmanville, Mich., is said to be without a physician, the only doctor in the place having inherited some money, and sought a more desirable residence.

The Case of the So-called Vermont Medical College of Rutland has come up before the Supreme Court, and the legality of diploma-selling in Vermont will now be settled.

St. Luke's Hospital and the New York Cancer Hospital received each a bequest of $100,000, from the late John Jacob Astor.

American Medical Students and German Universities.—The Berlin University has, it is reported, refused to acknowledge the diplomas of six American medical students, and has voted that American medical students shall not be matriculated until by an examination they shall have shown proper educational qualifications.

Dr. W. B. Rogers has been appointed President of the Board of Health of Memphis, Tenn.

The Nervous-Debility Quacks of England have fallen upon evil times. The first prosecution of one of them under the new Indecent Advertisements Act took place recently in Bristol, where a man was charged with advertising "Dr. Lilly's vital tonic, the restorer of vitality, cures nervous debility, losses, etc.," there being no such registered person as "Dr. Lilly." The defendant was also fined ten shillings for the indecent advertisement, and £10 for practising and representing himself to be a medical practitioner.

A School for Studying Lunacy.—The London County Council has decided to erect an hospital, not for the storage of lunatics, but for the treatment of psychological disease, and the instruction of specialists therein. There will be a staff of skilled experts, and the Council is prepared to spend $10,000 a year on it.

The Johns Hopkins Hospital Reports.—The first and second numbers of these proposed reports have been received. They are well printed and contain ten articles, six by Dr. Osler. The sudden gush of medical literature from Johns Hopkins, in the shape of hospital reports and bulletins promises to make a very considerable annual increment to American medical literature. We regret, however, to find good material buried in hospital reports, which documents are, in our opinion, a form of literary superfœtation, only excusable on the ground that they advertise the hospital.

The Mott Memorial Lectures.—The first course of public lectures to be given at the Mott Memorial Library, No. 64 Madison Avenue, began on Monday, March 3d, at 5 P.M., and will continue on Mondays and Thursdays until April 3d. The lectures will be by well-known instructors and scientists upon scientific subjects and will be fully illustrated by experiments, lantern views, and drawings. The Lecture Committee comprises a number of the best known ladies and gentlemen of the city. The subjects as chosen constitute a very attractive programme, while the lecturers are F. Cope Whitehouse, A.M.; Professor W. Le Conte Stevens; H. Carrington Bolton, Ph.D.; Professor John K. Rees; N. L. Britton, Ph.D.; Professor John J. Stevenson, M.D., Ph.D.; Professor Edward S. Morse; and George F. King, Esq. As is well known to most of our readers, the Library of the New York State Medical Association and the Mott Memorial Library have become united under one management.

The Formation of Special Societies is progressing in Germany. The latest is the Vienna Dermatological Society.

Ancient Therapeutics.—Mark Twain, in the February number of *Harper's Magazine*, entertains his readers with some accounts of former medical nostrums, which can be paralleled in the library of many a physician of historical tastes. He quotes largely from an old book called "A Dictionary of Medicine," printed in 1745. He says it was captured by Northern troops in 1861, in Virginia, where it was still believed in and followed. Here is an extract: "A certain merchant about forty Years of Age, of a Melancholic Habit, and deeply involved in the Cares of the World, was, during the Dog-days, seiz'd with a violent pain of his Head, which some time after oblig'd him to keep his Bed. I, being call'd, order'd Venesection in the Arms, the Application of Leeches to the Vessels of his Nostrils. Forehead, and Temples, as also to those behind his Ears; I likewise prescrib'd the Application of Cupping-glasses, with Scarification to his Back: But, notwithstanding these Precautions, he dy'd." Whereupon Mr. Clemens remarks: "Now that we know what the physician did when he wanted to relieve a headache, it is no trouble to infer that if he wanted to comfort a man that had the stomach-ache he disembowelled him."

Professor Daniel Mollière, a well-known surgeon of Lyons, France, died recently from the effects of the influenza.

Foot-Ball Casualties in England during five months, as collected by a *Lancet* correspondent, are as follows: Deaths, 13. Fractures: Legs, 15; arms, 4; collar-bones, 11. Injuries: Spines, 3; nose, 1; knee, 1; ankle, 1; cheek, 1. This is a most extraordinary record, and it is surprising that it excites so little comment. If foot-ball were electric light, the whole country would be boiling with indignation over "the deadly foot-ball," "the lethal sphere," etc.

Popular Lectures.—The members of the Montgomery County (Pa.) Medical Society purpose to give a course of twelve lectures on the care of the sick, including accidents and emergencies, and twelve on physiology and hygiene. The lectures will be free to the citizens of Morristown.

The Tennessee State Medical Society will hold its fifty-seventh annual meeting April 8th, 9th, and 10th, in Chattanooga. The Society was organized in 1831, and this would have been the sixtieth meeting had not the war put an interruption to the annual reunions for a time.

Changes in the University Hospital, Philadelphia.—The authorities in charge of the University Hospital propose some extensive alterations, which, it is hoped, will be improvements. A new mortuary building has been erected and will be opened soon. The lecture-room in this building, for the purpose of conducting autopsies, is said to be one of the best in the country. The hospital is to be re-plastered, repaired, and refitted, and new rooms for the reception of private patients are to be built, new elevators put in, and various other changes will be made in the furnishing and fitting up of the wards and the rooms.

A Medical College is to be established in Wales.

Many Graduates of Many Kinds.—In one short day in the city of Indianapolis, four medical colleges had commencements, each one turning out quite a number of graduates. The names of these colleges are the Central College of Physicians and Surgeons, the Medical College of Indiana, the Indiana Eclectic Medical College, and the Physio-Medical College.

Foreign Doctors and Dentists in France.—The French Minister of Public Instruction has declared officially that hereafter foreign doctors ought to submit their diplomas to the judgment of the French faculties, which would then decide whether they were on a parity with those granted to French practitioners. Furthermore, foreign medical men should be required to undergo the final examinations to which French candidates for the qualification to practise have to submit themselves. He admitted, however, that exceptions might be made for doctors practising in summer and winter resorts. With regard to dentists, he held that it would be well to insist upon residence for a term of three years at the house of a duly qualified French dentist, and registration at a faculty or school of medicine.

The New Hospital at Dartmouth.—The foundations of the Mary Hitchcock Memorial Hospital, to be built by Hiram Hitchcock, of New York, and named in memory of his wife, were laid this week.

The Death of Dr. Paul Niemeyer, a well-known writer and lecturer on hygiene, is announced. He was born at Magdeburg, March 9, 1832, and was for many years a lecturer and private tutor at the university at Leipsic.

American Ambulances.—A writer in the *Sun* says that the American ambulances, which were introduced into Paris a year or two ago, are now one of the recognized institutions of the French capital. People stand and cheer as they go along the street, and ambulance drills are given to all distinguished foreigners. The French Government has given full credit to America for the ideas which at present prevail on the subject, and, indeed, the words "American Ambulance" appear on the sides of the hospital wagons.

Dr. Edward K. Henschel, of this city, died at his residence here on February 28th. Dr. Henschel graduated at the College of Physicians and Surgeons in this city in 1872, and subsequently studied abroad. He acquired a large practice, but two years ago kidney troubles compelled him to visit Europe in search of recuperation. After several months of careful nursing Dr. Henschel started for America in comparatively good health, but while aboard the Bourgogne, en route to New York, he met with injuries that undoubtedly shortened his life. During a heavy gale he was thrown from his feet and knocked senseless. From these injuries he never recovered.

The New York Hospital Collections for the past eleven years show a pretty steady increase in the amount of money given, as may be seen by the following table:

1879	$26,455 07	1885	$46,085 38
1880	44,371 97	1886	53,051 98
1881	42,535 45	1887	50,449 15
1882	30,699 90	1888	52,039 63
1883	43,962 74	1889	57,021 45
1884	36,542 75		

The Successor of Sir William Gull.—There has been considerable speculation in London concerning Sir William Gull's successor as Physician in Ordinary to the Queen. The vacancy will be filled, as a matter of course, says the London *World*, by Dr. Richard Douglas Powell, who is the senior of the three Physicians Extraordinary. When once a medical man has been appointed Physician Extraordinary, his promotion to be Physician in Ordinary is a mere matter of course and question of seniority, and the next vacancy will be filled by Dr. George Johnson. The Queen has four Physicians in Ordinary, and each receives a salary of £200 a year, but, in reality, her Majesty does not call any of them except Sir William Jenner, and Dr. James Reid, her resident medical attendant.

A Hospital for Working Girls.—There is a movement on foot in Boston to establish a hospital, or endow several beds in some existing institution, for the benefit of working-women and girls. The endowment is to be in memory, and to bear the name of the late actress, Mrs. Vincent. Edwin Booth is said to have started the subscription for this purpose with $1,000.

Report on Sanitary Regulations of the Pan-American Congress.—The Committee on Sanitary Regulations of the Pan-American Congress has made a unanimous report in which it condemns absolute isolation in preventing the spread of epidemics, and recommends in its stead the disinfection of all articles from infected localities before they are permitted to be imported into healthy places. The following propositions have been adopted by the Congress on recommendation of the committee:

"That, taking the existing state of the relations between the nations of America, it is as practicable as it is advisable for the promotion of these relations to establish perfect accord with respect to sanitary regulations.

"That the greater part of the ports of South America on the Atlantic are guided and governed by the decisions of the International Sanitary Convention of Rio Janeiro of 1887.

"That although it does not appear that the plans of the Sanitary Congress of Lima of 1889 have passed into the category of international compacts, it is to be hoped that they will be accepted by the Governments that participated in the said Congress, because those plans were discussed and approved by medical men of acknowledged ability.

"That the Sanitary Convention of Rio Janeiro of 1887 and the draft of the Congress of Lima of 1889 agree in their essential provisions to such an extent that it may be said they constitute one set of rules and regulations.

"That if these were duly observed in all America they would prevent under any circumstances the conflict which usually arises between the obligation to care for the public health and the principle of freedom of communication between countries.

"That the nations of Central and North America were not represented either in the Sanitary Convention of Rio Janeiro or the Congress of Lima, but that they might easily accept and apply to their respective ports on both oceans the sanitary regulations before cited."

A draft of the provisions adopted by the Sanitary Conventions of Rio Janeiro and Lima forms an appendix to the report.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, February 24, 1890.

ALEXANDER S. HUNTER, M.D., PRESIDENT, IN THE CHAIR.

Disciplining Members.—Charges having been preferred to the Committee on Ethics against two members for very unseemly advertising, it was recommended by this committee and the comitia minora that they be expelled. Carried unanimously.

Eye-strain: Its Causes and Symptoms. An Easy, Accurate, and Inexpensive Method for its Detection by the General Practitioner.—DR. FRANCIS VALK read a paper with this title. The desirability of being able to detect errors of refraction by the general practitioner was shown by a statement of Dr. Thomson in a paper read at the last meeting of the Society, that "certain afferent impulses may cause functional nervous diseases," Dr. Hughlings Jackson had said, "since six cranial nerves, and the sympathetic nerve, supply the eye and its apparatus, it is evident that without a good knowledge of eye diseases the thorough investigation of many morbid affections of the nervous system cannot be carried out."

Reflex Nervous Phenomena.—The author was inclined to believe that the peripheral irritation caused by eye-strain, either when the intrinsic or extrinsic muscles were involved, might cause other nervous phenomena, and might be the exciting cause even of functional chorea and epilepsy. Certainly in all these cases the physician should inform himself whether there was any error of refraction which might produce eye-strain—a condition which, if present, should be corrected.

Recently Dr. J. H. Woodward, of Vermont, had published a monograph in which he gave the histories of one hundred and fifty cases of headache, vertigo, lachrymation, nausea, epileptiform convulsions, migraine, neuralgia, etc., in many of which he was able to note the final results after the use of suitable glasses, and he reported that at least eighty-five per cent. were relieved, and only sixteen per cent. failed to find relief. All of these cases had certain refractive errors which, Dr. Valk said, could have been easily recognized by the method which he was about to demonstrate.

Relative Frequency of Different Forms of Refraction.—The late Dr. Agnew had found in 1,060 cases of eye-strain, 281 normal or emmetropic eyes; about 400 hyperopic, 145 myopic, the remainder, 234, with unequal curvature of the cornea or astigmatic in various degrees.

Definitions.—Inasmuch as he was not addressing specialists, the author defined the emmetropic, hyperopic, myopic, and astigmatic eye. The emmetropic was the normal eye, in which when at rest the rays of light coming from an object were focalized on the retina. This was a condition of refraction not often met, and one which seldom caused any symptoms of eye-strain. In hyperopia the optic axis was too short, the principal focus being behind the retina, and consequently perfect vision was not possible without continued exercise of the ciliary muscle. In the myopic eye the axis was too long, and we found the retina beyond the focal distance. In this case there might be no strain at certain distances, yet under particular circumstances or a faulty correction, the eye might feel the strain on the ciliary muscle.

Simple astigmatism was produced by unequal curvature in the cornea, and compound astigmatism by this condition and faulty distance antero-posteriorly, as existed in hyperopia and myopia. To counteract the change in curvature of the cornea there must be unequal contraction of the ciliary muscle in the different meridians, which caused strain and irritation. The ciliary muscle being composed of radiating and circular fibres, contracted, and thus controlled the refractive power of the crystalline lens in such a way as to cause the rays of light entering the eye to focus upon the macula lutea of the retina. The chief and determining cause of eye-strain lay, then, with this muscle.

Subjective Symptoms of Eye-strain.—The most common was headache, generally in the frontal region and about the eyes, sometimes in the occipital, sometimes not specially located. The patient usually could read only for short intervals, shorter at night. He complained that the eyes were weak, they "burned, watered, and had a strained feeling." There might be floating specks before the eyes, the lids stuck together in the morning, there might be dizzy sensations, and even vertigo. When the extrinsic muscles of the eye were at fault, the headache was more likely to be in the occipital region.

A Simple Test Retinoscopy.—In examining the eye by retinoscopy, the patient was placed in a dark room, with a good light above and a little behind, the examiner sitting about forty inches in front of him, looking through a piece of plain mirror at a spot where the quicksilver had been rubbed off an eighth of an inch in diameter. While looking through the aperture the reflected pencil of light from the mirror is projected into the eye, while the patient looks beyond and just past the examiner's ear. We see the pupillary space changed from its black color to that of a beautiful orange-red, with some indistinct apparent shadows at the edge of the pupil as the mirror is moved. Now slightly and rapidly rotate the mirror on its vertical or horizontal axis, being careful not to move the head, and if there is any existing error of refraction in the examined eye, we will notice that the bright illuminated point of the retina moves across the pupillary space, followed by what appears to be a dark shadow, but which is really a portion of the retina not illuminated. It is the movement of this bright area which will decide for us the error of refraction, or tell us if the refraction of the examined eye is normal. If we turn the mirror to the right on the vertical axis, and we notice that the illuminated area moves in the same direction, then the eye must be hyperopic, and the image we see is a virtual image of the illuminated part of the retina.

If with the same rotation of the mirror we find that this movement of the bright area is in the opposite direction, that is, as we turn the mirror to the right the illuminated area seems to pass to the left, then the examined eye must be myopic, and we see a real inverted image of the illuminated part of the retina.

If we notice that these two movements of the reflex are very rapid, uncertain, very bright, filling the entire pupillary space, the examined eye will be almost if not fully emmetropic, there will be no existing error of refraction. This being considered the normal eye, should not require glasses.

If astigmatism were present, there would be a difference in the movements of the retinal reflex. Suppose that we find in the vertical meridian the movements of the reflex are in the same direction as the mirror is rotated, then the refraction in that meridian is hyperopic; but if in the horizontal meridian, as the mirror is turned, we find that the retinal reflex moves in an opposite direction, this meridian must then be myopic, etc.

This method, he said, had come from France, had been largely adopted in England, less in this country, was regarded with disfavor in Germany. The author had found it reliable and easy of application, but agreed with others who had said it required accuracy and experience to show its greatest efficiency. He recited some cases in his own practice, and one described by Dr. Wiesner, his assistant. He had not time to enter upon the theory of retinoscopy, nor to give the details of correcting errors of refraction by glasses.

Retinoscopy not Practical for the General Practitioner.—DR. DAVID WEBSTER said the only thing he could at all criticise in the paper was the recommendation of retinoscopy for use by the general practitioner. It was difficult to learn in a way to be useful, even for

an oculist. Besides, not more than five per cent. of persons examined by him showed emmetropic, or supposed normal vision. Further, if there were symptoms apparently due to eye-strain, and the general practitioner found an error of refraction by this method, he would have to send the patient to an oculist anyway, for more exact examination and the selection of glasses, and this might as well be done in the first place.

Asthenopia in Normal Refraction.—Dr. O. D. Pomeroy had seen eye-strain and accompanying symptoms even in emmetropic eyes. One could not expect to escape these troubles, even though he had normal vision, when he used his eyes excessively in bookkeeping or literary pursuits. He spoke of a number of eye-symptoms due to errors of refraction, but said, if a patient had hypermetropia or insufficiency unaccompanied by symptoms, he would let him alone.

Regarding the method of determining errors of refraction described by the author, he thought it was quite impractical, for by it one only determined the presence of myopia, hyperopia, or astigmatism, not the degree, and other methods had finally to be resorted to. "Better take a good method and master it, and then we will be good for something as diagnosticians."

Ocular Headache.—Dr. J. A. Andrews read his views on the influence of eye-strain in causing certain symptoms, particularly nervous, and said this question was one very close to the interests of the ophthalmological surgeon. Certainly a majority of persons who sought his advice, especially in private practice, did so because of some error of refraction or condition of the muscular apparatus of the eye producing a complexity of symptoms. He did not think retinoscopy practical in the hands of the general physician.

Dr. Emil Gruening thought the method recommended by the author, especially without dilatation of the pupil, not sufficiently exact nor practical.

Dr. Lambert thought it sufficiently exact, and he had devised measures for making it more convenient for the specialist, but he could not recommend it for use by the general practitioner.

Dr. Bucklin expressed similar views, and said the most reliable information for the general practitioner was obtained by asking the patient what were his symptoms, and whether they were aggravated by use of the eyes. If they were so aggravated, send him to an oculist, who himself found it difficult enough to determine just the refraction and what glasses were best adapted to the case.

Dr. Holcombe related some experience going to prove the value of treatment directed to the ocular muscles in correcting certain symptoms relating to the eyes, etc., and Dr. Valk closed the discussion, upholding the statement that retinoscopy was the most practical method yet devised by which the general practitioner could determine the presence of errors of refraction. What further step should be taken could then be decided upon.

The Society adopted a resolution, endorsing the bill before the Legislature for the prevention of blindness and report of cases of purulent ophthalmia in infants by nurses and midwives.

Dr. Ralph Waldo read the report of the delegates to the recent meeting of the State Society.

An Incentive to Begetting many Children.—French Canadians are celebrated for their large families, and now we may expect to find them outdoing themselves in this respect as the state proposes to pay for children when presented in batches of a dozen. A bill has been passed by the Legislature of Quebec granting one hundred acres of land to every farmer who has twelve living children. Several applications for this premium have already been made, one of the first being by a M. Léon Phénises, who, although but thirty-eight years of age, is the happy father of twelve healthy children and the owner of a $5,000 farm.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, February 27, 1890.

Egbert H. Grandin, M.D., Chairman.

Ovarian and Intra ligamentous Cysts.—Dr. George M. Edebohls presented three specimens, the first being from a patient who for a year before she consulted him had noticed progressive enlargement of the abdomen, mostly limited to the right inguinal region. There was also pain and rather profuse menstruation. On examination he found the uterus crowded against the symphysis by a soft, semi-fluctuating tumor which occupied the upper two-thirds of the pelvic cavity and extended somewhat into the abdominal cavity. It was diagnosticated to be an intra-ligamentous cystoma. There was another tumor at the right of the uterus, four or five inches in diameter, very slightly fluctuating. It could be rolled about all over the abdomen, but gradually settled again in the right iliac region. It was supposed to be a cystoma of the right ovary. The operation verified the diagnosis with regard to both tumors, but the one last mentioned was found connected by a long pedicle with the left instead of the right ovary. Both were removed without first emptying their contents. The operation had been performed three weeks ago, and the patient had since done well.

Fibro-myoma of the Vagina.—The second specimen presented by Dr. Edebohls was of interest chiefly because of its rare situation. It was a fibro-myomata which had developed from the vagina. Subsequent to a miscarriage, three years before, the woman had noticed fulness at one of the labia, and two years before the operation the tumor projected between the labia. Dr. Ebebohls found its measurement to be an inch and three-quarters in the greatest diameter, and its pedicle springing from the posterior wall of the vagina, just above the entrance. The cervix and perinæum were badly lacerated (the woman had borne five children), and were repaired when the tumor was removed, six weeks ago. The pathologist reported that the tumor contained all the elements of the uterus, even to the utricular glands, which suggested the possibility of its having formerly been a uterine polypus, which became separated from the uterus and attached itself to the ruptured perinæum.

Excision of a Tenacious Hymen.—The third specimen consisted of a thick, tough hymen, which he removed from a young woman, lately married, who said her husband was unable to enter the vagina. Dr. Edebohls excised the hymen, which had been stretched and pushed up a distance like the inverted finger of a glove, and sewed together the mucous membrane of the vagina above and below, the line of incision by a continuous catgut suture. There was no further trouble.

Dr. A. F. Currier said he had excised the hymen in several cases, but had not thought it necessary to use a suture. He first stretched the orifice, and after the operation introduced a cotton plug.

The Chairman said, regarding the second specimen, that it must be very rare for a fibro-myoma to develop from the vaginal wall. The explanation suggested by Dr. Edebohls was a curious one.

Universal Handle for Uterine Electrodes.—Dr. A. H. Goelet presented a universal handle for uterine electrodes, both of the platinum and steel varieties. He also exhibited a platinum electrode, which he had made flat instead of round, in order to render it adaptable to the curve of the uterine canal, the round one of Apostoli being too stiff (and also costly) because of its weight.

The Treatment of Pelvic Hæmatocele and Hæmatoma.—Dr. A. H. Goelet then read a paper with this title, but limited his part of the discussion to the use of electricity. He thought all would admit that the usual treatment was most unsatisfactory, chiefly because of the slow progress toward recovery. By the electrical treatment he had been

able to shorten the period of convalescence and suffering of the patient.

By hæmatocele he meant an effusion of blood into the pelvic peritonæum, although it might become encysted; and by hæmatoma, an effusion into the cellular tissue outside the peritonæum.

Laparotomy was justifiable only when collapse was imminent from intra-abdominal hemorrhage. He had been quoted as operating for hæmatoma, but it was in a case in which he and an authority on pelvic tumors mistook it for one of cyst. He believed the patient would have recovered in a shorter time without an operation.

Four Indications for Treatment.—1. To check the hemorrhage. 2. To produce coagulation of the effused blood as quickly as possible, and thus prevent recurrence of the hemorrhage. 3. To relieve pain and inflammatory complications. 4. To effect absorption of the clot and prevent the formation of an abscess. He might add a fifth indication, namely, to shorten the confinement to bed as much as possible.

Difference between the two Poles.—In speaking of the electrical treatment it should be remembered that the two poles in their action on the living tissues were directly antagonistic. The positive relieved pain and congestion; the negative tended rather to produce these effects. The alkalies were attracted to the negative pole; the acids to the positive. The fluids attracted to the negative pole produced an influence somewhat like tincture of iodine; the acids going to the positive pole produced coagulation, the greatest effect being at the point of contact, but also extending some distance around. The positive pole produced absorption, but the negative pole was more effective in this direction.

When to Use the Positive Pole.—The positive pole should be employed at first, and rest in the horizontal position until all danger from hemorrhage had ceased. The positive pole promptly relieved congestion; this prevented further effusion, and also promoted absorption of the effused blood. It could be employed in two ways. The first was through the vagina, the current long continued, commencing with twenty or thirty milliampères, increasing gradually to one hundred. The negative pole was so placed as to include the mass directly between it and the positive pole. He used a rheostat. The application might be increased once or twice a day, according to the exigencies of the case, until the end was accomplished.

Galvano-puncture.—The second method consisted in positive vaginal galvano-puncture, the puncture being made by a very small needle insulated up to the tissues penetrated. A strong current—say fifty milliampères—could be used five or ten minutes. It might be repeated in from three to six days. In small hæmatoma often but one treatment was all that was necessary. He restricted this method of using galvanism to hæmatoma. He did not apply it to hæmatocele. For puncture the point should always be of platinum. The use of the positive pole also gave relief from pain and prevented inflammatory complications.

When to Use the Negative Pole.—To hasten absorption during convalescence it might become necessary to use the negative pole; but usually the case progressed rapidly enough under the positive pole, employed as already described, especially if galvano-puncture had been practised. It was to be borne in mind that the needle simply penetrated the capsule, and was not passed on into the clot. The rapid absorption which took place under the positive pole might be explained by the fact that the mass became negative. If the negative pole were used it should be only after the clot had become firm and all inflammatory action had subsided. It was also contra-indicated when any pain was present, and when pain followed its use. Negative galvano-puncture, however, should never be practised in these cases. Absorption took place in from one week to ten days.

Suppurating Hæmatoma.—If suppuration took place in a hæmatoma it should be evacuated and drained per vaginum. In suppurating hæmatocele laparotomy was indicated.

Laparotomy in Hæmatocele.—The discussion was participated in by Drs. Currier, Ralph Waldo, J. H. Fruitnight, J. H. Emerson, H. C. Coe, Elizabeth Cushier, and the Chairman, all of whom directed their remarks to the general treatment of pelvic hæmatoma and hæmatocele, professing to no experience with the electrical treatment. Dr. Cushier had drained successfully per vaginum in four cases, but most of those who expressed their views on this subject preferred laparotomy when urgent symptoms were present.

How Soon after Delivery does the Responsibility of the Accoucheur Cease.—Dr. H. C. Coe read the paper. It covered a larger ground than the title indicated. Many of the complaints for which women consulted gynecologists were due to too early dismissal of confinement cases by the physician, but more especially, as appeared from the paper, to want of proper management during the time the patient was under the physician's care. He was convinced that there were excellent general practitioners who still paid as little attention to whether there was a rupture of the perinæum after labor as did midwives. As to laceration of the cervix, he was satisfied that not one physician out of ten inquired after a labor regarding that point. The author thought in every case where there was laceration of the perinæum it should be repaired at once. The immediate operation for laceration of the cervix should not be done except in severe cases where there was danger from hemorrhage. But if the cervix were supposed to be injured, strict cleanliness and vaginal antisepsis should be kept up for days subsequently by the use of the douche and the introduction against the cervix of a suppository of iodoform. After closing the tear in the perinæum a pad of absorbent cotton or bichloride gauze should be applied, and the urine drawn every six hours.

If the uterus showed a tendency to remain large and to fall backward, it was his custom to introduce a pessary for two or three months, on the principle that "A stitch in time saves nine." If there were any leucorrhœa, back ache, or other symptoms, the patient should be kept under observation until the physician could feel assured that the pelvic organs had returned to a normal state. It was not uncommon, he thought, to mistake mild forms of septic infection, which might lead to abscess of the broad ligament, etc., for difficulties connected with lactation. He believed the majority of cases of pyosalpinx in married women had their origin in labor or abortion, and it was unnecessary in these patients, as a rule, to seek a cause in gonorrhœa.

Responsibility not Measured by Days nor Weeks.—It would thus be seen that the accoucheur's responsibility was not to be measured by days nor weeks. It ceased only when all puerperal lesions had been repaired and evil consequences averted. He thought the patient should be frankly informed of any lesions present, and of probable after troubles, that they might, if possible, be averted. Only in this way could we hope to escape the implacable resentment which women felt for the medical attendant should they subsequently have any illness which could be attributed to the confinement.

Primary Perineorrhaphy not always Successful.—Dr. Currier approved of the primary operation on the perinæum, but said it was not always successful, and if it was not for the kindliness of nature in cases of labor in which accidents had happened, there would be more women having an "implacable resentment" to their physicians.

Relaxed Tissues as a Cause of Backward Displacement.—He had seen more than one case in which backward displacement of the uterus could be attributed simply to weight and relaxed condition of the organ subsequent to labor. Physicians were too likely to forget that such cases were much benefited by general treatment.

Delays Cutting the Cord.—Dr. Wood had found much

better results since adopting the method of not cutting the cord until pulsation had ceased; of keeping the hand constantly on the uterus an hour after expulsion of the placenta, sometimes even two hours; of removing all clots from the vagina; of sewing up any tear in the perinæum.

Laceration of the Cervix Invariable.—With regard to laceration of the cervix, he believed it was present in some degree in every case of labor. He had had none in which it was absent. Vaginal injections were employed only when specially indicated. He believed they interfered with healing of the wounds. No person was allowed to touch the patient but himself for three days. She must not raise the shoulders from the bed for two or three days, as it would interfere with healing of lacerated surfaces. A little blood clotted in the cul-de-sac, which, if it was allowed to remain, supported the cervix and aided union of its surfaces.

The patient should retain the recumbent posture for three weeks, and if she got up the fourth week a pad should be inserted beneath the cervix. By thus keeping the uterus up, the laceration of the cervix, although it were extensive, would be likely to heal.

Use Plenty of Sutures.—Dr. Edebohls had learned from experience that the whole tear in the perinæum and vagina should be thoroughly closed by primary operation, beginning by inserting a suture at the vaginal end of the tear and proceeding outward toward the skin. Sometimes seven or eight sutures were necessary.

Mild Septicæmia.—Dr. Ralph Waldo thought the diagnosis of mild septicæmia was not readily made. At any rate many cases were overlooked, and indeed led to the development of pyosalpinx which might subsequently demand laparotomy. He approved of primary perineorrhaphy, but opposed primary trachelorrhaphy except for severe hemorrhage.

Dr. Fruitnight said that theoretically the responsibility of the accoucheur ceased only when the parturient organs had been restored to the condition which was present before pregnancy; practically, however, the physician found tradition prevented his continuing his visits so long.

When Puerperal Fever Prevailed in Bellevue Hospital some years ago, nine or ten patients dying of the disease every month, Dr. J. L. Perry was house-physician in one of the wards, Dr. Murray being his assistant, and not one of their patients died. They kept the hand on the uterus after expulsion of the placenta one or two hours, in one case all night, employed antiseptic precautions, saw the patients every two hours. The strict discipline suggested by Dr. Coe was proper, but could not be enforced in private practice.

It Depends on Payment of the Bill.—Dr. A. M. Jacobus had found that no matter what amount of care the physician gave his patients, his responsibility in the opinion of those who refused to pay their bills would not cease for the next three years. He did not think it advisable to keep the patient on her back fourteen days. She should sit up to urinate, and thus allow clots to escape from the vagina.

A Frank Confession not always Good for the Pocket-book.—Dr. Goelet always taught the need of sewing up any laceration of the perinæum, and once by request, aided a young physician to do so in three cases. The result was that the young man's patients and their friends left him subsequently, to employ midwives, in whose care they never had a rupture, or, at least, were not told of it.

In the Nursery and Child's Hospital Dr. Hance had found the physician's responsibility usually much shortened since they had adopted the most approved antiseptic management of women during confinement. In some instances they had not been able to repair the perinæum until two or four hours after delivery, yet union had then taken place satisfactorily. Like Dr. Edebohls, they made the repair thorough.

Objects to the Iodoform Suppository.—The Chairman said he must again protest against the use of the iodoform suppository. It was not antiseptic, and was especially objectionable in that its odor would obscure the fetor pertaining to septic endometritis should this arise. Regarding the advice given, keep the patient on her back three weeks, he had been taught to do that; but now believed, with Dr. Goodell, that it was advisable to lift her into the sitting posture two or three times a day after the third day, and thus insure drainage of the vagina.

Correspondence.

A SUGGESTION IN OPHTHALMOLOGICAL TERMINOLOGY.

To the Editor of the Medical Record.

Sir: The substitution of the terms "temporal" and "nasal" for "homonymous" and "crossed" in the definition of diplopia. While the use of the word "crossed" in the definition of one form of diplopia is sufficiently epigrammatic and clear to bear its meaning on its face, such is not the case with the term "homonymous." He who has not knowledge of the Greek adjective ὁμός, the same, must make use of some original form of mnemonics to fix this word in his mind. There is an artificial diplopia produced by the use of prisms, and there is a natural one caused by paralysis of one or more of the ocular muscles. If the image, say, of the right eye, stands on the right side, the term "homonymous" is ordinarily used. The term "temporal," used under these circumstances, would render the meaning obvious and clear, for the image of one eye is projected outward toward the temple of that side of the head. When the double vision is "crossed," *i.e.*, the right image is on the left side, and *vice versa*, the term "nasal," if used, will represent a proper antithesis to "temporal," and be equally obvious and clear as the term "crossed," for the image is projected toward the nose. The use of a purely Greek word as antithetic to an English one is an inconsistency, and possesses no merit. It seems to me that the substitution of the term "temporal" for "homonymous," and "nasal" for "crossed," in the definition of diplopia is reasonable. This substitution was suggested to me in the course of conversation by Dr. W. B. Davis, Captain, United States Army.

John Herbert Claiborne, M.D.

WHAT WAS TRIED TO REMEDY THE ABUSE OF MEDICAL CHARITY.

To the Editor of the Medical Record.

Sir: In a recent issue of your journal there is an editorial reference to the meeting of the profession held a few years ago, at the Academy, to discuss the advisability of co-operation with the "Charity Organization Society."

The writer was one of those who responded to the call or invitation of that society, and was present during the session, and was one that felt aggrieved—not at the society, for it was evident to those present that the action of the gentlemen composing it was taken in good faith; and the statistics presented, and the evidence adduced, proved conclusively the need and the advantages of such co-operation—but at the coterie of dispensary habitués and their friends, gathered together for the purpose, and who captured the meeting in neat style. It could hardly have been done with more skill by General Butler himself, and their success proved conclusively that they missed their vocation.

The meeting was hardly organized before the motion to refer to a committee, to be appointed by the Chair, consisting of representatives of the various dispensaries—and two of the most outrageous offenders—was made, and supported by a characteristic speech. It was seconded, of course, and carried almost unanimously. It appeared, therefore, that we had been invited there to witness the killing of the reform movement, and to grace

the triumph of our enemies, instead of deliberating on and devising measures to check them.

The apparent unanimity of the reported proceedings was doubtlessly due to the surprise occasioned by the audacity of the gentlemen. Such political methods are comparatively rare in medical meetings.

The writer did, however, attempt to stay the flood, by proposing an amendment to what you are pleased to term "the American method" of appointing a committee. The amendment embodying a representation of the other side.

It was stated, in explanation of the proposed amendment, that, as the original motion gave representation to the hospitals and dispensaries that were chiefly responsible for the abuses, the tramps and dead-beats—the chief beneficiaries—ought also to be represented on the committee.

The motion to refer, as above stated, was carried, the committee appointed, and then the meeting adjourned.

The committee have performed their duty nobly, successfully. They chloroformed the movement into its peaceful, everlasting sleep; and, no doubt, if anyone should raise a voice of censure, they would plead "that they used all proper precautions; that they had all the known restoratives at hand; that every effort was made at resuscitation; but that it 'perished by the will O' God, or, heart-failure.'" MEDICUS.

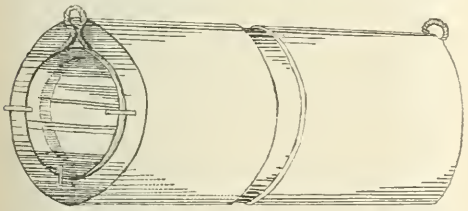
New Instruments.

A WORKING MODEL OF THE EYE.

BY R. J. PHILLIPS, M.D.,

CHIEF OF CLINIC, EYE DEPARTMENT OF PHILADELPHIA POLYCLINIC AND COLLEGE FOR GRADUATES IN MEDICINE.

A SMALL camera which I have recently constructed as a model of the eye has proven of so much use in illustrating to students the elementary facts regarding the refraction of the eye, the various forms of ametropia, and the methods of determining the degree of the latter, that I have thought a description of it might be of value. In the perfection of the geometrical and mathematical explanation of the refraction of the eye contained in the



modern text-books, the student seems in danger of losing sight of the fact that we have, in the camera obscura, a working model of the eye which can teach the facts of refraction better than any other method can hope to do. With the facts plainly before him, the student naturally seeks their explanation. Many working models of the eye have been made; but they are all so costly as to be far beyond the reach of the majority of students; in that which I describe I have utilized the lenses of the test-case, thereby reducing the cost of the instrument to a mere trifle. It consists of a cylinder of card-board, three inches long and about two inches in diameter, over which slide two other cylinders, each one and a half inch long. One end of each of the latter cylinders is closed by a stout wooden diaphragm; of which one has a hole one and an eighth inch, the other a hole of three-fourths of an inch in diameter, in its centre. In front of these holes are hooks for holding lenses. The interior of the instrument is well blackened. We have thus a cylindrical box, whose length may be varied from three inches to nearly six inches. If a +19 D. or + 10 D. lens be placed before one of the openings in the box, the ground-glass disk usually found in the test-case before the other, and the board cylinders be shifted until a clear image of distant objects is formed on the ground glass, we have a model of the eye in a condition of emmetropia. Either end of the model may be used as the front; giving two sizes of the opening which represents the pupil. If we slightly lengthen the box, myopia with its blurred image is shown. Placing a concave glass before the lens clears the image; so does bringing the model near the object. A definite amount of myopia may be produced in the model by substituting a stronger lens for that used in representing emmetropia. Hypermetropia can likewise be shown in two ways. Astigmatism is, of course, represented by placing a spherical and a cylindrical lens at one of the openings. In practising the shadow-test, the metal disk of the test-case is substituted for the ground glass at the back of the model. In the direct method a disk of card-board containing fine print, a series of lines, or a drawing of the fundus may be so placed. It is, perhaps, in illustrating the shadow-test that the model is most useful; the action of light in the pupil being shown with great distinctness. A single example will serve to show the application of this test. Placing in the front of the model a + 10 D. lens, we shift the board cylinders until we have a clear image of distant objects on the ground glass (emmetropia). Substituting for the + 10 D. lens a + 9 D. with + 2 D. cyl. axis 180°, we have mixed astigmatism, with the meridian of greatest refraction at ninety degrees. We replace the ground-glass disk by the metal disk, and reflect light into the model with the plane mirror. At a short distance from the model this light appears as a perpendicular band, moving rapidly and easily with the mirror from side to side; slowly and with difficulty in the direction of its length. At the distance of one metre (the point of reversal for the myopic meridian) the band of light can still be moved from side to side but not in the direction of its length. Beyond that distance the light appears to move against the mirror when moved up and down, but remains with the mirror for all distances when moved from side to side. The advantage to the beginner in using the model rather than the eye itself lies in its better illumination, and the consequent distinctness of the movements; and in the fact that the student is able to produce any form of ametropia at will. The model may be obtained from Mr. H. C. Boden, the optician, of Thirteenth and Walnut Streets, either without lenses, or, for use in the common schools, in which its value will be readily seen, fitted with a suitable lens and screen.

18 NORTH THIRTY-EIGHTH STREET, PHILADELPHIA.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 23 to March 1, 1890.

By direction of the Secretary of War a board of medical officers, to consist of Major Charles Smart, Surgeon; Captain Valery Havard, Assistant Surgeon; Captain Louis Brechemin, Assistant Surgeon, is appointed to meet at Fort Leavenworth, Kan., on March 15, 1890, or as soon thereafter as practicable, for the purpose of preparing a manual of drill and instruction for the members of the Hospital Corps, and to examine the equipment of the corps with a view to its improvement. Par. 9, S. O. 47, A. G. O., Washington, D. C., February 26, 1890.

LORING, LEONARD Y., Major and Surgeon, having been found incapacitated for active service by an army retiring board, by direction of the Secretary of War, the extension of leave of absence on surgeon's certificate of disability granted him in S. O. 34, February 10, 1890, from this office, is still further extended until further orders on account of disability. Par. 3, S. O. 46, A. G. O., Washington, D. C., February 25, 1890.

Smith, Joseph R., Lieutenant-Colonel and Surgeon. Promoted to be Surgeon with rank of Colonel, February 9, 1890.

Bache, Dallas, Major and Surgeon. Promoted to be Surgeon with rank of Lieutenant-Colonel, February 9, 1890.

Harvey, Philip F., Captain and Assistant Surgeon. Promoted to be Surgeon with rank of Major, February 9, 1890.

Patzki, J. H., Major and Surgeon. The leave of absence for seven days granted in Orders 25, Fort Huachuca, Ariz., February 12, 1890, to take effect the 14th instant, is extended twenty-three days. Par. 1, S. O. 18, Department of Arizona, February 17, 1890.

Kneedler, William L., Captain and Assistant Surgeon. Upon being relieved from duty by Captain Robinson, will report at Jackson Barracks, La., for duty at that station, relieving First Lieutenant Freeman V. Walker, Assistant Surgeon; upon being relieved Assistant Surgeon Walker will report at Fort D. A. Russell, Wyo., for duty at that station. Par. 4, S. O. 43, A. G. O., February 20, 1890.

Robinson, Samuel Q., Captain and Assistant Surgeon, now on duty at Fort Hamilton, N. Y., is relieved from duty in the Division of the Atlantic, and will report in person to the Superintendent United States Military Academy, West Point, N. Y., for temporary duty at the Academy, to relieve Captain William L. Kneedler, Assistant Surgeon. Par. 4, S. O. 43, A. G. O., February 20, 1890.

Official List of Changes in the Medical Corps of the United States Navy for the week ending March 1, 1890.

Rush, C. W., Passed Assistant Surgeon. Ordered to the Navy Yard, New York.

Auzal, E. W., Passed Assistant Surgeon. Ordered to the Galena.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 1, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	17	6
Scarlet fever	96	8
Cerebro-spinal meningitis	4	2

Cholera	0	0

"Clinica" is the name of a new monthly medical journal in the Roumanian language, published at Bucharest. The editor is Professor Assaky.

Treatment of Dandruff.—A solution of chloral hydrate, five grains to the ounce, is recommended for the cure of dandruff. It is to be applied night and morning in small quantity and allowed to dry on the hair.

Local Medication of the Drum-Membrane.—One of the greatest difficulties with which the oral surgeon has to contend is to get patients to make applications properly in cases of otorrhœa. Syringing is seldom done effectually, while the attempt to introduce powders by the process of blowing is usually a farce, for the powder either fills the mouth and nose of the amateur operator or is deposited for the most part in the recesses of the concha. Dr. A. M. Shield, of the Charing Cross Hospital, London, describes, in *The Practitioner* for November, 1889, a method of making local applications in these cases which can hardly fail of being more effectual than most of those now in vogue. It consists of the introduction of little pellets, the size of swan-shot, made of cocoa-butter, with which is incorporated whatever medicament it is desired to employ. The method of application is thus described by Dr. Shield: "At night-time, the patient lying on the opposite side, one of the pellets is quickly taken up and dropped into the meatus. The tragus being drawn backward and shaken, the little ball soon enters the canal. A plug of wool is then introduced, and the patient sleeps in the same position. The parts are thus for several hours impregnated with the agents introduced. The basis is soft, and so readily melts in the fingers that the pellets must be kept in a cool place, and rapidly dropped into the ear. Should they stick on the walls of the canal, the point of a fine dry brush can be used to push them onward, and this instrument can be intrusted to unskilled hands." The chief objection to this method would seem to be the danger of clogging up the meatus by the oily matter and the dirt and epithelial débris which it will collect. This necessitates special attention to keeping the parts clean; but cleanliness is necessary in any case, and the method proposed by the author certainly secures an effectual application of the medicament employed to the perforated membrana tympani.

How some try to Pass the Naval Medical Board.—Medical Director Delavan Bloodgood, United States Navy, in responding to the toast of the Medical Corps of the Navy at the banquet of the Medical Society of the State of New York, among many other good things said: "A wrong impression has gotten abroad that great and increasing gaps exist in our ranks. There are a moderate number of vacancies in the grade of assistant surgeon, but more than enough available candidates for the places are booked and awaiting examination. Now I desire to explain a bit concerning our required examination, and the bruit that it is too 'exacting.' The origin of the complaint cannot better be demonstrated than by some quotations from the records of the Examining Board. Bear in mind, gentlemen, please, that all these candidates, whose essays I will cite, hold the degree of Doctor of Medicine, and many of them the baccalaureate also, and several were practitioners of from one to three years' standing. Thus one writes in making his application: 'I am a graduate of the Medical College of ——, and I think I can fill the bill. Is there any vacancies now? Is the examination as rigid as reported? I am a lover of surgery and hope I will fill the bill.' One aspirant was asked in the oral examination, 'Who was Hannibal?' 'Hannibal was a Hun and a Vandal,' he replied; next, 'How did Hannibal get into Spain?' and answered: 'He must have crossed around through Asia.' Question to another: 'Who succeeded Julius Cæsar?' 'Pontius Pilate,' was his prompt reply. Another answered that 'the Suez Canal connects the Atlantic and Pacific Oceans at Panama.' One stated that 'Galen, who was born in the eighteenth century, discovered the circulation of the blood;' another mentioned that 'Harvey was a celebrated electrician.' One doctor had never heard of Jenner, but another knew all about him, and said that Jenner lived before Christ and practised vaccination in India, where he was born. One, when directed to write a prescription in Latin, said, 'We don't write Latin prescriptions out in —— County.' Another sent this note from his writing-table to the president of the Board: 'Sir, you ask me in your question, "What is the mediastinum?" As I never heard of it I would like to have your advice about withdrawing from the examination.' Another wrote in answer that 'phimosis is a disease coming on in old age.' One, who had been in practice for two years in a large city, closed his remarkably original treatise on diarrhœa thus: 'But the best treatment of all

to be given is them old opium pills found in shops and other places about town.' And here is another doctor's exhaustive thesis on opium : 'Opium is grown extensively, that is the tree from which the gum opium is obtained, in the West Indies. The tree grows a small papula, which is of a gummy consistence; this is then gathered and the inside of the papula is then formed upon cakes or lumps, in which way it is transported to market. It is also grown in some of those foreign countries like China, which produces a very superior article. I find that opium is not borne as well by the stomic as codei. This active salt, which is very soluble in aqua, gives us a form of giving the effects of narcotism in very minute doses.' These candidates, and very many others like them, and but only they, denounce our examinations as too exacting; and this is the way that one of them, not unlike the worm, turned and addressed the president of the Board : 'Sir, in your conversation with me you made a simile, the fore part of which I have forgotten because I was so forcibly struck with the latter part, which was that something was like a man having won a girl's love he then cared nothing for it. Owing to your at the time superior position I said nothing. As I said nothing you may have thought that I agreed with you. The difference in our position was removed by your rejecting me as a candidate. I now say that I do not agree with the sentiment. On the contrary, I believe that if there is one thing more than another which relieves life of its barrenness and renders it worth living it is the love of a true woman, and the longer a man has won that love, and the more he has fathomed its depth, the more he will value it, if he be a man. And further allow me to say that in my opinion the most despicable individual on the face of God's earth is he who under the guise of a pleasing exterior seeks to win a pure girl's love, simply that he may have the diabolical pleasure of trampling upon it. I could not leave you under the impression that I had such an opinion of my fellow-men, in general, as agreement with you would signify. Should even twenty years' service in the Navy force upon me such an opinion, I thank you for rejecting me; contact with my fellow-men in private life will, I am sure, show me a better side of human nature than that. I have had my say. Yours, M. D.'"

Pseudo-urinary Affections.—The Paris correspondent of the *British Medical Journal* states that Dr. Bazy publishes some interesting particulars concerning a class of affections M. Guyon terms "faux urinaires" (pseudo-urinary troubles). Sometimes the symptoms clearly indicate uterine, rectal, or anal affections. Most often, however, they exhibit characteristics which differentiate them from this class of illnesses, though they have one common point of resemblance, the nervous system is disturbed, and general paralysis or hysteria, etc., may ensue. Bazy has examined several cases without detecting any lesion; he has collected notes on seven cases, which he classes as glycosuria, not diabetes. Except in one instance, there were no symptoms indicating that the urine should be tested for sugar; in this knee-jerk was absent. M. Bazy affirms that this symptom occurs even in slight glycosuria. Pseudo-glycosuria resembles glycosuria by the existent nervous troubles common to both forms. M. Bazy says pseudo-urinary conditions are easily diagnosed. The general condition is frequently good, and glycosuria generally disappears when a proper diet is strictly followed. Sugar is often only detected after meals, and the proportion in twenty-four hours is not important.

Rupture of the Gall-bladder.—At a late meeting of the Medical Society of London, Mr. Haslam read the notes of the case of a man, aged sixty-three, who was admitted into the Birmingham General Hospital on August 5, 1889, with strangulated inguinal hernia on the right side. This was relieved by operation, and he left the hospital on August 27th, feeling perfectly well. Within twenty-four hours he was again admitted, with symptoms of peritonitis, and an inguinal hernia on the left side was down and constricted, but reducible by careful taxis. As the symptoms increased in severity the abdomen was opened in the middle line, and the peritoneum found acutely inflamed and containing a little bile-stained fluid. The distention of the intestines was so great, and the man's condition so bad, that no attempt could be made to find the rent in the gall-bladder. Death occurred in eight hours. At the necropsy the gall-bladder was found to be extremely thin at its upper aspect over a space as large as a sixpence, and in the centre of this there was a small perforation. The parts about the transverse colon and stomach were very adherent, and the omentum reached into the left hernial sac. The cause of the rupture of the gall-bladder was probably the dragging due to the tension put upon the great omentum by the descent of the left hernia, or else the vomiting may have caused it. There was considerable difficulty in getting a history, but, so far as could be made out, the descent of the hernia preceded the peritoneal symptoms by a short time only. Mr. Haslam said that a probe had been passed through the ducts, which were quite free from obstruction. A piece of omentum was found lying free in the sac on the left side, and some coils of intestine just above it. There was no lesion of the intestine. He thought the dragging of the omentum across the stomach might have given a jerk sufficient to cause a laceration of the weakened wall.—*The British Medical Journal.*

An Obstetrical Experience.—The late Dr. Ellwood Wilson, of Philadelphia, is said to have personally delivered more than fourteen thousand women, nine deliveries having been accomplished on one occasion within twenty-four hours. In addition to this he saw about twenty thousand other obstetrical cases in consultation with his colleagues.

Mercurial Flannel.—Dr. Carles gives a detailed account of the method of preparing mercurial flannel, an article which appears to be coming into use in France. Its introduction is due to Professor Merget, of Bordeaux, who, in his recent thesis for the degree of Doctor of Medicine, shows that when frictions are made with mercurial ointment the mercury is not absorbed by the healthy skin, and that the metal acts only by the vapors which it spreads, and which are introduced into the system by means of the respiratory passages. The inconveniences attending the use of mercurial applications are well known; they are sometimes difficult to apply, and occasionally they cause cutaneous eruptions and salivation. Professor Merget has proposed to replace them by applications of thick tissues, upon which is fixed an adherent deposit of mercury reduced chemically to an impalpable powder, and placed in conditions most suitable for it to become slowly vaporized. Flannel is the material used for this purpose. It is first treated with a solution of sodium carbonate in order to free it from grease, and thus prepared it is dipped into a saturated solution of mercurous nitrate and afterward into liquor ammoniæ; this solution precipitates the mercury in the tissues of the flannel as mercurous ammonium. To make use of the mercurial flannel it is sufficient to place a square of ten inches on one side near the respiratory passages. Although the system is thus in direct contact with the mercurial vapors, it is not saturated by them, for they are rapidly eliminated by the renal and intestinal excretions, and thus an equilibrium is maintained. Experience has shown that respiring these vapors every night and leaving them off during the day, sick people and those in good health support them without the least inconvenience during several months. It is necessary to observe that if the mercurial dust from the flannel be inhaled with the vapors, salivation is rapidly produced. The piece of flannel, therefore, must be inclosed in a bag of some light tissue, so as to prevent the dusting out of the mercurial powder. The flannel thus protected is placed under the patient's head if he sleeps on his side, or

upon his chest if he lies upon his back. This mercurial flannel will give sensible vapors of mercury which can be recognized by tests for years. It weakens, however, sensibly every day when in contact with the hot body. It is therefore necessary to renew it about every three weeks. It can also be used as an application to the skin in cutaneous affections due to parasites. For this purpose it is applied in the form of a glove, a sleeve, or bandage.—*The British Medical Journal.*

The Prophylaxis of Phthisis.—At a recent meeting of the Académie de Médecine M. Villemin read a report on the prophylaxis of phthisis. The author said that of all the maladies phthisis, or, more strictly speaking, tuberculosis, in all its forms made the most victims. In large towns it frequently caused a fourth of the deaths. It was, moreover, essentially infectious, and the infection was due to a microbe *sui generis*, which, independently of direct transmission, penetrated into the organism by the lungs, the digestive canal by the air and food, the skin and mucous membranes by scratches, wounds, etc. The most frequent and most redoubtable source of contagion resides in the expectoration of phthisical patients, and then more especially when it is dry and reduced, so to speak, to powder, which change promptly takes place when, as among the lower class, the floor, walls, and bedclothes are covered with it. Later, when the floor is swept this dust rises and enters the lungs, deposits itself on everything, and constitutes thereby a permanent danger to those who sojourn in this tainted atmosphere. The dejections of patients contained also the contagious principle. From the foregoing it resulted that very particular precautions should be taken in the treatment of phthisical patients. Spittoons should be invariably used, and every day the contents should be emptied into the fire, and then rinsed with boiling water. All linen soiled should not be left to dry, but be plunged at once into boiling water. Sleeping with the patient to be strictly forbidden, and after the decease the room should be thoroughly disinfected. M. Villemin recognized that the parasite of the malady can also be introduced by the food, milk, meat, and the blood of certain animals (cows, rabbits, fowl). The milk should be the object of special care on the part of mothers and nurses (two thousand children die annually in Paris under two years from tuberculosis); it should be always boiled; the same need not be said of goats' or asses' milk, which is infinitely less dangerous. The meat should be rigorously inspected by the officers provided by the law. The habit of drinking fresh-drawn blood at the slaughter-houses (a habit much indulged in by the French for anæmia) should be strongly condemned. Discussion of this important paper was, at its conclusion, deferred till next week.—*Medical Press.*

Systemic Infection by Oidium Albicans.—MM. G. Roux and Linossier, who have been making a thorough morphological and biological examination of the oidium albicans, reported to the Société des Sciences Médicales of Lyons during October the results they had obtained with regard to the occurrence of systemic infection (*The British Medical Journal*). They used artificial cultivations grown on carrots, the fungus under these conditions growing only in the torular form. Two rabbits were inoculated by injection into the auricular vein. One animal remained perfectly well until the fifteenth day, when it suddenly became paraplegic and rapidly died. The other, which received a smaller quantity of the culture, was more rapidly affected; on the day after the inoculation it was dull, passed but little urine, and the head and ears were inclined to the left; after the second day no urine was passed; and on the fourth day the animal lay on its left side, owing, it was thought, to giddiness. In both animals the cortical substance of the kidneys and the muscular substance of the heart contained numerous small white nodules like large miliary tubercules, and consisting of tangled masses of the filaments which, under certain conditions are known to develop from the torular form of oidium albicans. In neither case were any lesions of the central nervous system or of the labyrinthine canals discovered, but MM. Roux and Linossier point out the resemblance of the symptoms in the second rabbit to those observed by Lichtheim after injection of *aspergillus*. These observations extend and confirm those of Klemperer, and lend support to the view, based upon a few scattered clinical records, that the oïdium, which is usually strictly limited to the epithelium, occasionally enters the circulation, and may give rise to systemic infection and serious visceral lesions—even multiple cerebral abscess (Zenker, Robbert).

The Babies' Hospital.—The first annual report of the Babies' Hospital, covering the period from June 16, 1888, to December 1, 1889, has been issued, and makes a very creditable showing. The number of patients treated during that time was 214, the total of hospital attendance amounting to 4,393 days. It might at first sight seem unnatural that a mother would trust her young infant to the care of strangers, but Dr. Holt states in his report that an investigation of 91 consecutive cases showed the following imperative reasons: In 23 cases the father was out of work; in 20 cases the father was dead; in 5 cases sick in a hospital; in 1 case he was in prison in Sing Sing, sentenced for sixteen years; making a total of 49 cases in which the father was incapacitated from supporting the child. In 15 casesthe mother had been completely deserted by the father. In 2 cases the mother was insane; in 6, dead: and in 6, sick and in a hospital.

Old Ale.—Some beer was recently discovered, walled up in the cellars of a brewery at Burton-on-Trent, which had been brewed in the year 1798. It was found to be in good condition, resembling sherry more than it did a malt liquor.

Help for Influenza Sufferers.—The Paris Municipal Council has voted the appropriation of $8,000 for the relief of the families of those who have died, or been long ill from the effects of *la grippe*. The cable reports that the Pope has ordered the bishops of the countries which have been visited by the epidemic to excuse from the observance of the Lenten fast all those who have suffered from the influenza in an aggravated form, and who are still in a weakened state as a result thereof.

Pork and Consumption.—The President of the Ohio State Sanitary Association, in a recent paper, inveighed against the use of pork as an article of diet, holding that it was probably the direct cause of pulmonary phthisis. The editor of the *Medical Advance* seems to assent to this view, and says that he has never seen a case of tuberculosis in an orthodox Jew. Investigation has shown that Polish Jews are not exempt from pulmonary phthisis, and it is by no means uncommon to see in the children of Polish Jews the unmistakable evidences of tuberculous disease of the bones or joints.

What can a Vegetarian Eat?—In a letter to the *Medical Press* the Secretary of the Vegetarian Society says that there is more or less confusion in the minds of many people as to what constitutes the dietary of a vegetarian. It does not consist in an exclusively vegetable diet, for the vegetarian may eat, at his option, all animal products that have not possessed animal life, *e.g.*, milk, butter, cheese, eggs, honey, and the like.

The Eighth Congress of Russian Naturalists and Physicians was held in St. Petersburg in January, the opening session being on the ninth of that month (new style). The members of the Congress were welcomed by Professor A. Beketoff, on behalf of the Committee on Organization and of the citizens of St. Petersburg. Professor Mendeleyeff was elected President of the Congress, but yielded on account of ill health to Professor Beketoff. Professor Dokutchayeff was re-elected Secretary.

THE EVOLUTION OF THE LOCAL VENEREAL DISEASES.[1]

By G. FRANK LYDSTON, M.D.,

CHICAGO, ILL.

It was invariably tanght until quite recently that the viruses of chancroid and gonorrhœa were specific entities which were always and invariably the same, their inoculation being followed under all circumstances by similar and typical results. Indeed, I myself accepted this view so confidently that it is with some hesitancy that I will endeavor to present views that are diametrically opposed to those which I formerly believed to be correct. When Drs. Taylor and Bumstead, in their excellent work upon the venereal diseases, advocated the doctrine that the chancroidal virus was not a specific entity, and that chancroidal ulcerations differed in degree only, rather than kind, from ulcers of a simple character, there were very few, indeed, who did not antagonize their views. It is only within a very short time that I have been convinced, from observation and experience, that chancroid and gonorrhœa are diseases which may arise *de novo*, and which, in the true sense of the term, are not specific. It is only by the acceptance of this theory that it is possible to understand something of the origin of chancroid and gonorrhœa, and which we certainly cannot do under the old and generally accepted doctrine of specificity.

While we may not be able to positively demonstrate the origin of the poisons of all infectious diseases, it is difficult to comprehend that a "specific" poison has always existed in any case, and it is certainly a great step in the advancement of medical science when we become able to trace the poison of any particular specific disease to its source. We have not been able to do this with many diseases, for it is fully as difficult to understand the circumstances under which certain morbid entities affecting the human body sprang into existence as it is to comprehend the precise conditions under which vitality itself first made its appearance in matter hitherto inert. A few of the morbid conditions affecting animal life have fortunately been traced to their origin, and, through the germ theory, we have at last begun to see a little light in regard to the origin of infectious diseases. Even at the present day, however, very few scientists are looking in the proper direction for the origin of disease, for if we admit that the germs of disease are living entities, why is it not logical for us to bring to bear upon them the same laws of evolutionary progression, differentiation, and development that we now apply to all other living creatures?

Disease is incident to the life of every animal, and as we study the evolution of the animal, so should we study the evolution of its diseases. Every phase of animal development and progression is subject to adverse elements of various kinds; thus each animal is relentlessly pursued by foes of a higher or lower evolutionary development. Man, with his superior power, born of knowledge, has been able to contend successfully with all of those elements which are inimical to his welfare, with the exception of those apparently insignificant little organisms—the germs of disease. As man himself has become differentiated through varying circumstances of environment, so have his foes become differentiated; hence he has become more susceptible to the inroads of certain forms of disease-germs, but less susceptible to others; certain varieties of germs have become extinct, while new forms have been developed; others, again, have become so modified as to bear almost no resemblance to the parent stock. By pursuing this line of study we may eventually find that many diseases which are now apparently quite dissimilar, have become so by the differentiation of the germs upon which they depend, and perhaps may discover the circumstances which have brought about such differentiation.

In applying this theory to chancroid, I first desire to call your attention to a few analogical arguments that are certainly striking. We will take as our point of departure diseases of a known or alleged specific nature, and see if we cannot find elements in two forms of the same disease which are more dissimilar than are simple genital ulcers and chancroid In small-pox we note several degrees of severity, from a varioloid, in which there perhaps exists but a single pustule, to the variola hæmorrhagica, or maligna, which is so fatal to life. The resemblance between these two extremes is very slight, yet they are the same disease. Or, to go still farther, note the difference between small-pox and vaccinia. Not much resemblance between the two you will admit, yet the poison of the latter is a derivative of the former, and by its action the human system is rendered insusceptible to the attacks of its more vigorous and noxious ancestor.

In scarlatina we have all grades of severity, from the walking form, in which one would hardly know that the child is ailing, to the scarlatina anginosa, or maligna, in which the life of the little victim is so rapidly destroyed. A singular fact is that in the severe forms of scarlet fever the angina assumes characteristics so severe, and of so peculiar an appearance, that the doctor is compelled to say, "This child also has diphtheria." Do you believe that the system of the child could be a field for strife between two infections constitutional diseases of so pronounced a type? I do not; but I am convinced that these cases are an illustration of the manner in which certain diseases, supposed to be separate and distinct, are co-related; and, furthermore, of the possibility of their development *de novo*.

Typhoid and typhus fevers have numerous degrees of severity, the extremes of which are strikingly dissimilar, although the *materies morbi* is invariably the same. We know, too, that typhoid and typhus fevers may develop *de novo*, under favorable circumstances of environment.[1]

Malarial fevers vary in severity from a slight ague shake followed by fever to the pernicious type which speedily destroys life. Clinically, malarial and typhoid fevers are frequently confused.[2]

Septic infection in surgical diseases may result in one of several degrees of severity of blood-poisoning, from the slight febrile disturbance, which was formerly termed "traumatic fever," to the overpowering and speedily fatal septæmia, which is so nearly identical to snake-bite in its effects upon the blood. Interposed between the two we have acute and chronic pyæmia. These phases of disease differ widely, yet they are one and the same, and due to the same cause.[3] Erysipelas is a disease which may vary

[1] Read at the meeting of the McDowell Medical Society, Henderson, Ky., November 11, 1889.

[1] This was strikingly illustrated by the epidemic of typhus fever which occurred in New York City in 1880–81.

[2] When absorbed by the lungs hospital miasm has been known to produce effects closely resembling malarial poisoning, and curable by quinine.

[3] With due deference to the recently published papers of Dr. Senn upon pyæmia, in which, if I interpret him correctly, an opposite view is expressed.

in type from the slight form of inflammation which is hardly more than an erythema to such a severe form as that which sometimes affects the scrotum, and not only causes sloughing but often a fatal result. Can we detect the slightest resemblance between the two? I think not; yet they are the same disease. Inoculate your finger with blood drawn from a patient with erysipelas of the face, and you may escape erysipelas entirely; if you do not it is apt to occur in a mild form. If, on the other hand, you inoculate yourself with the secretions from a sloughing scrotum, and you do not die of septæmia, the least you can expect is phlegmonous erysipelas of a severe and dangerous type.

I would also call to your attention the vast differences which exist between the different forms of puerperal disease; thus, we meet with cases of peritonitis, cellulitis, phlebitis, and acute fatal septæmia, all due to the varying conditions and effects of the same *materies morbi*.

Further illustrations are, perhaps, unnecessary, but I must not omit the most important analogy of all, viz., diphtheria: Recent observations of a clinical character have shown us that the diphtheritic virus, germ, influence, or whatever you may choose to term it, is capable of producing many different phases of disease of the naso-pharynx, varying from a slight and, apparently, simple sore throat with little or no constitutional symptoms (catarrhal diphtheria), to an exudative malignant affection capable of rapidly destroying life, and invariably producing the most profound constitutional disturbance. We know that epidemics of simple sore throat are closely associated with epidemic diphtheria. With the coming and going of an epidemic of diphtheria especially, as well as during its maximum dissemination throughout a community, we observe many cases which, while they do not present the typical characters of diphtheria and the diphtheritic micrococcus cannot be found in the pharyngeal secretions,[1] are nevertheless due to the same influences as diphtheria proper. When diphtheria exists in a family of several persons, it is often observed that apparently simple sore throat will appear in some members of the family while others are affected by genuine diphtheria, and that the simple cases often become transformed into the more malignant type. Physicians in attendance upon cases of diphtheria are often affected by sore throat of greater or less severity; this being my own experience whenever I attend cases of this character for any length of time. A defective drain has been known to affect different members of the same family with morbid conditions of the throat, varying from trifling soreness to malignant diphtheria, and also with varying types of essential fever.[2]

I have mentioned these many facts, which are apparently so foreign to the subject of chancroid and gonorrhœa, to demonstrate the varying results which may be produced by the evolution of the same poison.

Now, what is the reason that these so-called specific poisons manifest themselves so differently under apparently identical circumstances? Simply a varying virulency of the poison upon the one hand, and varying susceptibility upon the other, these variations being comprehensible to me only upon the hypothesis of evolutionary changes in the germ as well as in its field of action, *i.e.*, the human system. Let us consider this hypothesis, and see if the variation of the phenomena of disease is not dependent upon a variation in what has heretofore been considered an unvarying entity—a specific germ—and if even the noxious or poisonous property of the germ may not be an ingraft upon it, or at least a matter of development. Let us take as our first point of departure those innocent germs, cocci, or, if you please, minute organized particles which everywhere exist in the atmosphere. These germs multiply by their own peculiar methods of procreation, and such multiplication is favored or opposed, as the case may be, according to their environment. Filth, heat, and moisture, and protection from air and light, favor the development of many such organisms. It is obvious that successive crops of germs are possessed of properties which diverge more or less from those of the parent stock. This is a universal law that applies to all living organisms. The newly acquired properties are modified or varied according to varying circumstances of environment. Whether it is the germs proper, their secretions or excretions, if such there be, or new and complex compounds produced by their action upon putrescible matter,[1] that produce their peculiar effects upon organisms more highly differentiated than themselves, it would be difficult to determine, but it is at least conceivable that, sooner or later in the process of evolution, germs are developed which are possessed of properties by virtue of which they are capable of producing definite effects upon the human system. Thus we have, by evolution, the spontaneous generation of so-called specific poisons. Now, do not understand me to say that the germs themselves are spontaneously developed, for while such an event is perhaps possible, it is as yet disputed by the best scientific authorities. What I do claim is, that the poison of disease may be developed by the evolution of, and acquirement of new and toxic properties, by germs which were primarily innocuous.

Having arrived at a stage of development when it is capable of producing definite morbid effects upon the system, we might suppose that this germ would cause invariably similar effects upon the human economy. But the law of evolution still follows the germ of disease in its tour of mischief, and as I have attempted to show you from a clinical standpoint, modifies the resulting phases of disease most markedly, independently of the special properties of the individual germ.

The conditions modifying the results of germ infection are, as nearly as I can understand them, as follows:

1st. The degree of virulency and vitality of the germ at the time it enters the tissues or blood of a human being.

2d. The inherent vitality of the individual, or his resisting power at the time of infection.

3d. Individual susceptibility to the particular disease represented by the germ, *i.e.*, idiosyncrasy.

4th. The condition of the eliminative apparatus of the person affected.

5th. If the disease germ has a special predilection for any particular tissue the result will be modified by the condition of that tissue at the time of its infection, *e.g.*, the typhoid bacillus and the comma bacillus of cholera Asiatica most readily affect those who have morbid conditions of the alimentary canal. Diphtheria is most apt to attack persons with acute or chronic naso-pharyngeal disease.

6th. And one of the most important of all, the number of germs and the length of time during which the patient is exposed to their influence.[2]

Although not usually attributed to evolutionary laws, some of these ideas in relation to the development of infectious diseases are already pervading the profession to a slight extent. Probably the nearest approach to a thorough exposition of the subject is an essay by Dr. De Correquer Griffith, of London, entitled the "Unity of Poison."[3] In this article the learned author has shown

[1] Some of the more recent investigations tend to show that there are several forms of micro-organisms found in diphtheria, none of which are characteristic, and all of which are found upon the normal mucous membranes.

[2] Lee, Dr. L. J. W.: Influence of Diathesis upon Contagion. New York MEDICAL RECORD, vol. xxv., No. v., p. 84.

[1] Ptomaines or leucomaines.

[2] Virchow has shown this to be eminently true of septæmia.

[3] Midland Medical Miscellany. As expressed by Griffith, this theory implies "the unity of poison and differentiation of resultant phenomena which we call symptoms—not because of any difference in the poison which may be the *origo mali* of so-called various diseases, but differentiations dependent upon the media through which the poison passes, or upon which it falls, the evolutions and development of that one poison being marked by new phases, new manifestations to which rightly we should not apply the expression separate diseases, but rather call them simply what they are, the various expressions of the evolutions of that unity of origin, whatever it may be, which has set them all agoing."

quite plainly the corelation of certain infectious diseases formerly supposed to be separate and distinct affections.

Now to attempt the application of this theory of the spontaneous development of specific poisons to the development of the viruses or germs of the local venereal diseases:

The idea that the chancroidal poison is one which has always been inseparable from the human species, is of course untenable. Somewhere along the line of our ancestry chancroid appeared, but at what time, history does not tell us. The human race in general must have begun existence with a considerable capital in the form of a healthy organization, and every disease which now affects unfortunate humanity must necessarily have developed since the species originated. As the races have become differentiated, or have diverged, new circumstances of environment have been encountered which have modified the organism of the human being, and in the course of evolutionary progression many and various diseases have arisen.

This fact has been due to—

1st. The appearance upon the scene of weaker and more susceptible organizations than those of the parent stock.

2d. Changes of telluric and climatic influences.

3d. Injuries and vicissitudes experienced in the struggle for existence, modifying the organisms of numerous individuals, such modifications being transmitted to their descendants.

4th. Varying character and quantity of food and drink, alcoholics within a considerable number of generations having exerted a marked influence.

5th. Varying sanitary circumstances, involving crowd poison, and other forms of noxious and contaminating animal matter.

6th. Varying personal hygiene, involving cleanliness, exposure to cold and wet, and other influences which may modify individual constitutions. The question of sexual habits here enters into consideration, and is necessarily of especial importance in its bearing upon the evolution of the venereal diseases.

7th. The gradual and certain evolution and differentiation of, and acquirement of new properties by, living germs.

So much for the acquirement of disease in general.[1] Gonorrhœa and chancroid have probably arisen in a manner precisely similar to the evolution of other infectious diseases, and while it is premature to say that the poisons of the two diseases are precisely identical, I am firmly convinced that they are different in degree rather than kind, and of a similar origin to say the least. We are not lacking in authorities who believe them to be precisely the same. Dr. R. W. Taylor is one of the leading authorities who claim that chancroid is not a specific disease in the sense that we speak of variola, and that, moreover, its poisonous secretion is precisely the same as that of gonorrhœa. Dr. F. R. Sturgis also holds this view.

The origin of gonorrhœa and chancroid must necessarily be the same, if the evolutionary theory of their origin be correct. The vagina of the female is as excellent a nidus or hotbed for the generation of poisons, as could be well imagined, and when we consider the large number of women who are affected by uterine or vaginal diseases, it is a matter of wonderment that the venereal affections are so few in number and manifestations.

There exists, even in perfectly healthy women, the circumstances of heat, moisture, protection from air and light, and the occurrence very often of local irritation in the form of excessive cohabitation. Superadd to these normal or quasi-normal conditions a suitable pabulum for the development of germs in the form of uterine or seminal discharges, and we are apt to have conditions decidedly detrimental, not only to the woman herself, but to the generative organ of any one with whom she may chance to have sexual congress. Few women are free from disease; indeed, the woman who is perfectly sound is a *rara avis*, and in the uterine discharges bacteria may develop and wax fat. Many women, through ignorance in some cases, through natural physical indifference in others, are exceedingly unclean, and allow both natural and unnatural secretions to accumulate until the condition of their sexual organs is indeed filthy. This is especially the case in the low class prostitute, and unfortunately is often the case among women who are respectable or quasi-respectable. As has been remarked by others, in connection with the subject of urethritis and chancroid, the high-toned prostitute is not so open to impeachment upon the score of uncleanliness as those of a lower grade. In a general way it may be said that if every man could view for himself the actual condition of most of the women of easy virtue with whom he is brought in contact, there would be a decided improvement in the moral tone of the community. I may also add, that with the present unhealthy manner of living in vogue among the fair sex, many young men would give up all romantic ideas of matrimony, if they could but inspect the object of their ambition through the speculum of the gynæcologist. So much for uncleanliness and disease, independent of the question of virtue and morals.

As the circumstances of uncleanliness, unhealthy secretions, local irritation, heat, moisture, and deprivation of free air and light favors the development of germs, and particularly those of decomposition, it may be readily understood that after a time such a bacterial development actually takes place in the vaginæ of some women. The innocuous germs of the atmosphere enter, and begin their work of procreation or multiplication in an environment scanty in its supply of oxygen,[1] decomposition occurs, and *pari passu* with it new germs appear upon the scene which differ from the parent stock; and so the process goes on until a very irritating poison is developed. If during this time, the discharge from a diseased urethra be added to the noxious materials, or if semen be deposited in this hot-bed of putrefaction, so much the better for a development of a "specific" poison. Selmi and Gautier have shown that poisonous alkaloids develop from putrefaction, and it is to these poisonous substances or ptomaïnes that I am inclined to attribute the trouble in gonorrhœa and chancroid. The decomposition of semen is especially likely to produce such a poison. If this be correct, it is to the products of the bacteria, rather than to the bacteria themselves, that we must attribute the results of chancroidal and gonorrhœal secretions. It is, therefore, assumed that while bacteria may be present in cases of gonorrhœa and chancroid, they are by no means necessarily so. This would explain why scientific observers have found bacteria or cocci in some cases, while they have been unable to do so in others. The varying degree of acridity and quantity of ptomaïnes, and the varying susceptibility of mucous membranes would explain the differences which appear to exist between gonorrhœa and chancroid, as well as between mild and severe types of the same disease.[2]

[1] Independently of the existence of the living germ, attention may be called to the generally unappreciated fact that all poisons act upon the animal body in accordance with physiological laws. The physician speaks of the physiological effects of his drugs, but strange to say, never of the physiological effects of the *materies morbi* of disease. The effects of poisons vary; thus, opium gives a wide range of results, from nervous stimulation to fatal coma, aconite varies in its effects from moderate sedation to cardiac paresis, malarial poison (or germs) from slight depression of the vital functions to fatal coma, and so on, ad infinitum. Again, some poisons have a local as well as constitutional effect, the local changes which they produce being also purely physiological. The science of medicine will never become philosophical until these facts are generally both appreciated and applied.

[1] "The experiments of Pasteur on chicken cholera are well-known. In hope of diminishing the infective power of this organism, he grew it in oxygen for a long time, and found not only that it produced a modified disease, but that this attack in most cases protected the animal from the effect of the organisms in their most virulent state!"—British Medical Journal, December 31, 1881, p. 1062.

[2] Eklund claims to have found in the secretions of both gonorrhœa and chancroid the characteristic "gonococcus" claimed to have been discovered by Neisser. He also describes mycelial woven filaments, termed ediophyton dictyodes. This parasite he also claims to have seen in both diseases. So far as it goes, this is confirmatory of the corelation of gonorrhœa and chancroid.

Now as to the conditions which modify the results of the virus generated *de novo* in the human vagina. These are as follows:

1st. It is obvious that much depends upon: *a*, the age of the decomposition; *b*, the degree of inflammation present; *c*, the frequency of coitus; *d*, the constitution and habits of the woman; *e*, the character of any semen or urethral discharges which may be deposited in the vagina; *f*, the degree of cleanliness of the woman.

2d. The amount and degree of virulency of the virus deposited upon the absorbent surface in another individual.

3d. The cleanliness, local and constitutional condition, habits, and sexual hygiene of the recipient of the cultivated virus.

4th. Individual predisposition.

With reference to the latter point, Dr. Jordan Lloyd has made the following excellent remarks: "There can be no doubt that some individuals contract—and even develop—venereal disease much more readily than do others. There can be no doubt that all physicians, from the nature of their calling, must, during the course of each year, be exposed to infection, of one kind and another many hundreds of times. I am not aware that physicians take any particular precautions in the way of protecting themselves from these influences. Immunity does not, in every case, depend upon their having already suffered from attacks of the various infectious diseases. How is it, then, that they so rarely become affected? It is because they have not the predisposition, whatever that word may mean; because their bodies do not present a suitable nidus for the growth and development of the germs of disease. Again, in a class of cases more closely allied, clinically and pathologically, to those under discussion, how often do we see among hospital officers men who are frequently developing crops of hospital furuncles on their hands and arms, others with constantly recurring sore throat, others with inflamed wounds and lymphatics from *post-mortem* abrasions, while at the same time and under precisely the same conditions there will be men who, year after year, remain free from all such troubles. Susceptibility of one class of individuals to certain poisonous influences, or insusceptibility of the other, must be the explanation. There is nothing more strange in it than in that of many of the well-known "idiosyncrasies;" for example, the poisonous effects of eggs and tobacco on certain persons."

This author further alludes to a certain class of persons who are familiar to every observant physician, as "suppurators." This is the class of people in whom, as we well know, wounds are more likely to heal by granulation than by first intention. Lloyd speaks of such persons as follows: "These people, apparently of robust health and iron constitutions, frequently have boils; when their lymphatic glands inflame, and they often do, the process more often terminates in suppuration than resolution; trivial wounds in such people do not dry up at once, they heal by granulation. I believe these suppurators contract venereal diseases where ordinary mortals escape them."[1]

Under the head of local conditions, phimosis, paraphimosis, balanitis, posthitis, and herpes not only modify the course of chancroid, but indubitably act as predisposing causes.

As a consequence of the widespread variation that exists in the conditions which I have given you, there may result from different inoculations of essentially the same products of decomposition different degrees of infection. Thus the disease acquired by exposure to such irritating material may be: 1st, a simple balanitis or balano-posthitis, or venereal vegetations; 2d, simple urethritis; 3d, a virulent urethritis; 4th, simple venereal ulcer indistinguishable from advanced herpes; 5th, classical chancroid. As you may imagine, I would find it difficult to show you just what variation in the development of the poison determined a gonorrhœa upon the one hand and a chancroid upon the other, but you will be perfectly safe in assuming that comparatively trifling differences in the circumstances of the development of the poison, as well as the differences in the local and constitutional condition and idiosyncrasies of patients, are amply sufficient to account for the difference in results. We will lay theoretical considerations aside for the moment and consider some of the clinical facts bearing out the theory of the development of chancroid and gonorrhœa *de novo*, and its corelation with other and simpler affections:

1st. It is found that the discharge from a virulent gonorrhœa, if confined by a tight prepuce, will cause quite severe inflammation and phimosis (*i.e.*, balano-posthitis). If not speedily relieved, excoriations and even ulcerations will result.

2d. The discharge from these lesions as well as that of gonorrhœa will oftentimes produce a pustule if auto-inoculated. It will generally produce some inflammation, and in experiments upon cachectic patients, I have known the tissues to break down in ulceration, which I am free to say appeared to me to be identical with some of the simpler cases of chancroid.

3d. The long-continued contact of these secretions with the mucous membrane often causes a crop of venereal warts. These frequently result from simple irritating secretions, *e.g.*, in pregnant women, and are an occasional complication of chancroid.

4th. Chancroid of the urethra is always attended by urethritis of greater or less severity.

5th. Gonorrhœa and chancroid are often associated in the same patient, either appearing at the same time or at such an interval that one may quite plausibly be due to infection by the secretion of the other.

6th. Both diseases are contracted from the same class of females, and often from the same woman. The higher class of prostitutes comparatively seldom convey either disease.

7th. I have myself examined women from whom both diseases had been contracted by different men at different times, and found them unclean, but at the same time free from both acute and chronic vaginitis and chancroid.

8th. Any of the urethral or genital lesions may be followed by suppurative bubo, differing chiefly in degree from virulent bubo. I have succeeded in auto-inoculating pus from a bubo secondary to severe balanitis.

9th. It is always difficult to say where simple genital ulcer terminates and chancroid begins. The test of auto-inoculation is hardly fair, as it simply tests the degree of virulency of the ulcer.

10th. The natural tendency of chancroid is to lose its "specificity" in a short time, and by a reversion of type to assume the benign characteristics of a simple ulcer.

I have been asked why all cases of gonorrhœa do not present ulcerations if the poison be the same as that of chancroid, and why urethral chancroids do not destroy the entire urethra. Now let me repeat that I believe the poisons are similar in origin and kind, but different in degree. To the first question I would answer, because the virus is not so highly developed as that which produces chancroid, and because, moreover, the urethra is a different structure from the glans penis, and is being frequently flushed out by the urine. For that matter, instead of pronouncing a case chancroid of the urethra and complicating urethritis, why not term it a gonorrhœa with ulceration? Perhaps the former diagnosis is confounding the *propter* with the *post*. In answer to the second question, I will state that the reason for the non-extension of urethral chancroid is the same as for its non-extension when it occurs upon the external surface of the genitals. As the virus invades increasing areas of healthy tissue, it necessarily meets with a resistance proportionate to the inherent vitality of the cells of the healthy tissue, and as a consequence, unless the local conditions are extremely favorable to the development of noxious and irritating

[1] Birmingham Medical Review, October, 1886.

secretions, the activity of the virus becomes exhausted after a time. In addition to this fact, we have the circumstance that there is more or less inflammation attendant upon chancroid, and as a result we have an exudative barrier of greater or less extent thrown up about the lesion, which opposes its progress to a certain extent. If, however, the patient be uncleanly or unhealthy, or if he be possessed of an idiosyncrasy predisposing to phagedæna, there is little vitality in the normal cells to oppose the inroads of the chancroidal process, and so slight an exudative formation that rapid destruction of tissue is liable to occur. These latter points must be taken into consideration in our studies and treatment of chancroidal phagedæna, and phagedenic bubo, as they will be of great assistance to us in actual practice.[1]

Opera House Block, Chicago, Ill.

REPORT OF TWO CASES OF DEATH IN YOUNG CHILDREN DURING THE ADMINISTRATION OF CHLOROFORM.

By HARRY M. SHERMAN, M.D.,

San Francisco, Cal.,

AND

V. P. GIBNEY, M.D.,

New York.

Dr. Sherman's Case.—On July 2, 1889, a boy, aged five years, was chloroformed at the Children's Hospital for the little operation of curetting some tuberculous sinuses. The chloroform was given in the usual way, on a towel held a short distance from the face. Anæsthesia was easily produced, and the sinuses curetted. At the bottom of these was found a small patch of carious bone, and, as the child began to move, a little more chloroform was put on a towel and the scoop applied to the bone. At this moment the child ceased to breathe, and the hemorrhage from the wound also stopped. The chloroform was removed, the child inverted, artificial respiration done for a few moments, when the functions were restored. Color returned to the face, and the danger seemed passed. It was only for a short time, however; after twenty or thirty respirations they again ceased, though no more chloroform was used. The heart stopped, the face blanched, and the pupils dilated. Artificial respiration was again practised, the child inverted, stimulants, such as whiskey, ammonia, digitalis, and nux vomica, were given by the hypodermic, hot and cold water alternately applied to the chest, and the battery was used, but nothing had the slightest effect, and, after an hour's work, the case was pronounced hopeless and further efforts abandoned.

The case had been an exceptionally bad one of hip-joint disease, and the hip had been exsected on June 1st, in the face of unfavorable symptoms and with an acknowledged bad prognosis. At first there had been no improvement, but for the three weeks preceding this accident there had been decided gain, and it was in the hope of making the gain more sure and more rapid that the operation was undertaken. It has been the custom at the hospital to give to the children, when the most painful stage of dressing was reached, a few whiffs of chloroform to produce a brief anæsthesia, and this custom had grown on us by immunity in its practice. The drug was always administered by a physician who gave attention only to that one thing, and there had never been any unpleasant effects, except in two cases a brief suspension of respiration, such as is sometimes seen when ether is used. This particular child had taken chloroform three times before, and on the third occasion he had supplied the second of the two cases mentioned; but the cessation was so slight that it was only remembered by the anæsthetizer after the fatal result of the last administration. At each of the three previous times more chloroform had been given, and anæsthesia had been longer than on the fatal occasion; for then anæsthesia had been established not longer than one and a half minute, and not more than a drachm of chloroform had been poured on the towel.

Remarks by Dr. Sherman.—If this case had been that of an adult, this history would have no particular interest. For among adults, chloroform frequently selects for its victims those who take it for a slight operation, who have taken it safely before, and who are not thoroughly anæsthetized when death occurs. But with children, chloroform has been considered a safe drug. This idea has been held by many in the profession, and by some, as Paget and Owen, is definitely stated as safe. It is possible that the result may have been the same if ether had been used, but this is not probable; and this case is reported to call attention to the fact that chloroform anæsthesia in children may be as dangerous, and what is worse, as treacherous as it is in the case of adults.

Dr. Gibney's Case.—A female child, two years of age, with a sacral spina bifida, was put under the influence of chloroform at my clinic on June 19, 1889. The patient was in excellent health, hearty and robust. The mother said it had never been sick. The chloroform was of good quality, and was administered in the usual way. That is, a small towel was saturated with the drug and held over the nose and mouth, but not in contact with the face. Within five minutes the child came under its influence, the pulse and respiration good. The hypodermic needle was thrust into the base of the tumor, and between six and seven drachms of serum mixed with a little blood were evacuated. The sac was injected with two drachms of what is known as Morton's fluid—iodine, ten grains, potassium iodidi, one half-drachm, glycerine, one ounce. The whole operation lasted about ten minutes, during which time the child was not profoundly anæsthetic, but cried out occasionally. The needle was withdrawn and collodion on cotton placed over the opening, a flannel roller applied around the body preparatory to a more snug dressing. At this time, however, the lips became blanched, the pulse feeble, and three minims of Magendie's solution of morphia were injected hypodermically. The breathing at once became more regular—pulse a little better. Very soon after this, almost immediately, the pulse grew feeble again, and forty minims of brandy were injected, when the patient ceased to breathe, and efforts at resuscitation, such as lifting the child by the feet, head down, artificial respiration, faradism, etc., proved of no avail.

This was about noon. In the afternoon the coroner held an inquest. Dr. Thacher, of the Polyclinic laboratory, made an autopsy, and no cause was found for death. The heart appeared normal in every particular. The iodine fluid did not enter the spinal canal, but was spread out over the sac. The kidneys were normal. Lungs normal. The coroner's verdict was death from chloroform.

It has been my custom for years to administer chloroform to children under the impression that death seldom or never occurred as a consequence. In correspondence with my friend, Dr. Sherman, I learned that he had had the same misfortune, and at my request, he sent me his case for publication. Naturally enough, since the events above recorded, I have encountered in medical literature references to the dangers of chloroform almost weekly. In the *Lancet*, October 19, 1889, I found this heading in a leader:

"Deaths under Chloroform.

"At an inquest recently held, the particulars were given of the death of a child, about six years of age, who succumbed to chloroform at the Victoria Hospital for Children. The child was admitted for treatment of dis-

[1] In his recent Lettsomian lectures, Mr. Jonathan Hutchinson expresses the opinion that chancroid usually occurs in persons whose systems have been impressed by syphilis at some period more or less remote. In other words, it is a mild manifestation of syphilis in a person who has already been sypbilized. This theory appears to be as untenable as it is striking.

ease affecting the left hip-joint. He had taken chloroform successfully upon two previous occasions, but on the day upon which the operation was to be performed the boy died after having inhaled the anæsthetic for fifteen minutes. A post-mortem examination was held, and the medical officer is reported to have said that there was fatty degeneration of the heart, liver, spleen, and kidneys. The death recorded illustrates the fallacy of two popular beliefs: first, that a person that can take chloroform with impunity upon one occasion will subsequently enjoy an immunity from danger; and, secondly, that children, who proverbially take chloroform so well, are less liable to fatal accidents from its effects than are adults."

In this same article, the last paragraph, we have the following:

"Almost before the ink is dry with which we record the above fatality, the report arrives of the death of a woman in a Dublin hospital, to whom it was proposed to administer chloroform as a preliminary to amputation of the thumb. It appears before she was fully anæsthetized she collapsed and died."

Alexander Wilson, the Administrator of Anæsthetics in the Manchester Royal Infirmary and Victoria Dental Hospital, in the *Lancet*, September 14, 1889, makes this statement:

"In the medical journals for the last ten years, there are reported one hundred and twenty (if not more) cases of death under chloroform. Many of these are very imperfectly described, but in at least forty-nine cases the patients were in good general health at the time of administration, and required the anæsthetic merely for the performance of some minor operation. Example—extraction of teeth (eleven cases of death), reduction of dislocations (nine cases), eye operations, fistulæ, and so on. In some fifty-nine cases death occurred before the commencement of the operation, and so was clearly due to the chloroform alone. In about twenty of the cases it is noted that chloroform had been successfully given on previous occasions; in one as many as eight different times before the fatal administration."

It was not my intention in reporting these cases to go into the subject of chloroform narcosis in adults, but to call attention to its administration in children, and to contribute my mite toward its discontinuance. In talking with a friend in Hartford, Dr. Wainright, on this subject, he tells me that he is in the habit of ordering it in the small vials, and that he never uses one vial twice, under the impression that the exposure to the atmosphere produces such alterations as to destroy its purity and greatly increase the danger. He believes that, "If Squibb's chloroform is used, and administered in an inhaler which produces the evaporation to the minimum (a dry tumbler in which is placed a small pocket handkerchief makes an admirable one), the danger is also reduced to the minimum, and it can be used with as little fear as ether." I have purposely given Dr. Wainright's opinion because of his prominence as a surgeon, and to meet the objections of some of those who say, "You do not give it properly," or "The chloroform is bad." After my interview with the doctor I addressed a letter to Dr. E. R. Squibb, of Brooklyn, asking a letter covering these points, and the following is his reply:

"Brooklyn, November 1, 1889.

"My dear Doctor: Your favor of the 31st is received, and I very gladly tell you all I know in regard to the keeping properties of the officinal purified chloroform. If this chloroform be kept in colorless glass and exposed to light, it is apt to undergo partial decomposition in the length of time proportionate to the brightness of the light, or the length of the exposure. But this decomposition, even when very slight indeed, is very perceptible in the odor of the chloroform, as it causes a very irritant effect of the air-passages in smelling it. Almost anyone in the habit of using chloroform at all, would detect this decomposition at once by the smell, and be pretty sure to reject any chloroform which had suffered this change.

"If kept from light, however, even in colorless bottles, this change does not occur within any reasonable length of time. If put up in amber-colored bottles, then no such change occurs even within two or three years, for I have samples now in my possession which have been kept in the ordinary amber-colored vials for many years, and are as good as when first put up.

"Next, in the ordinary use of chloroform so put up and so kept with a moderate degree of care, and only opened from time to time as portions of any particular package may be wanted for use, there is no perceptible change that takes place spontaneously in the chloroform, and a one-pound bottle or even a six-pound bottle may be used, a little at a time from beginning to end throughout, say—a year, without any perceptible change being discoverable in the chloroform which may remain in the bottle; at any time during this usage, even if such a bottle in use should be accidentally left unstopped or loosely stopped for any moderate periods of time during its use, and nothing should get into it except the ordinary atmosphere, it would not decompose nor be rendered unfit for use. If, however, as is the practice with some, a portion should be poured out of the bottle and be only partially used, and then the remainder poured back into the bottle after having been subjected to a very liberal contact of air, and perhaps the vessel breathed into, and then the remainder poured back into the bottle, the whole would soon become vitiated by this practice. It is not uncommon nowadays for physicians to give chloroform by simple inhalation from a wide-mouthed bottle, the bottle being held to the nose until the desired effect is obtained; then, if such chloroform as may remain unused be poured back into the bottle, it would of course vitiate the whole, because it would contain much of the products of respiration. All such residues should be thrown away and the wide-mouthed bottle be scrupulously cleansed before being used again, and there is no occasion for any great loss here, because no more than one or two drachms should be put in the bottle at any one time.

"I think I can confidently state to you, that any influence of the atmosphere upon the chloroform in an unstopped bottle, in any ordinary way of using, would not be hurtful to the chloroform nor dangerous to the patient, and I see no possible use that there could be in refusing to use chloroform a second or a third or a twentieth time from the same bottle, provided the bottle be managed with ordinary care and no residues of chloroform ever be returned to it.

"Very glad if I may be of service to you.

"Very truly yours,

"E. R. Squibb."

THE OPERATIVE TREATMENT OF ERYSIPELAS.[1]

By WILLY MEYER, M.D.,

SURGEON TO THE GERMAN AND NEW YORK SKIN AND CANCER HOSPITALS; CLINICAL PROFESSOR OF SURGERY TO THE WOMAN'S MEDICAL COLLEGE; INSTRUCTOR IN SURGERY AT THE POST-GRADUATE SCHOOL AND HOSPITAL

There has so comparatively little been said on this side of the ocean about the new operative treatment of erysipelas, and the method is such a good, reliable, and safe one, easily carried out by every general practitioner, that a few minutes may perhaps be granted to me to give a short report of my experience with the same.

As is well known, Volkmann had reported, by his assistant, Kraske, in 1880,[2] a number of cases of severe diffuse septic phlegmon cured by multiple incisions and scarifications. The favorable results achieved with this procedure have been frequently confirmed.

As it seemed probable that this method, if powerful

[1] Read at Albany, at the meeting of the Medical Society of the State of New York, February 5, 1890.

[2] Centralblatt f. Chirurgie, 1880, No. 17, p. 265.

enough to stop a diffuse infectious inflammation of the subcutaneous connective tissue, would act in a similar manner upon an infectious spreading inflammation of the skin, Kraske tried it for the cure of genuine erysipelas. His results were so encouraging that, in 1886, he had the history of three cases published,[1] which proved that an erysipelatous inflammation can also be prevented from spreading by surgical interference. The scarifications and multiple incisions, of one-third of an inch in length (from fifteen to twenty to the square inch) were made both in the skin involved and in the adjoining sound portions. If the erysipelas was very extensive, the scarifications were not made in the diseased area itself, but only

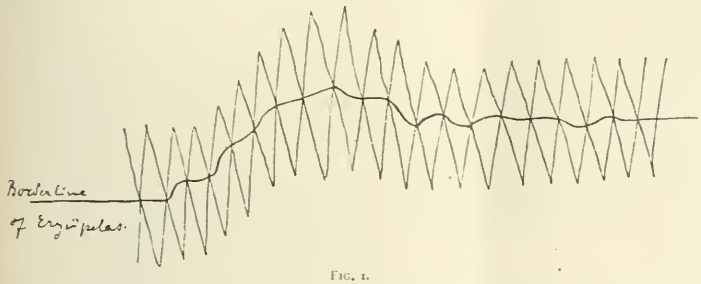

FIG. 1.

in the sound portion of the skin adjacent. In both cases the patient was anæsthetized. After the comparatively abundant bleeding had stopped, the skin was squeezed to press out the serum containing the infectious cocci, and at the same time irrigated with a five per cent. solution of carbolic acid. At last it was thoroughly washed with the same lotion, and dressed with moist compresses, soaked in a two and a half per cent. solution of carbolic acid. Dressings were changed once or twice a day. In two of the cases a single operation was sufficient to arrest the disease; in the third the operation was repeated twice before the inflammation was under control.

In 1887 Riedel[2] proposed to make superficial incisions in the border-line of the erysipelatous area only, because it has been shown that here alone the erysipelas cocci accumulate and proliferate, thus extending the inflammation. The incisions should just penetrate the chorion. They were about two inches long and one-sixth of an inch apart, one crossing the other at an angle of about forty-five degrees, the crossing-point being exactly on the border of the inflammation. Thus the whole invaded region was encircled with a net-work of cuts, not unlike a rail-fence (Fig. 1). It represents simply a double zigzag line, the points of which unite. For his dressings Riedel used gauze soaked in a sublimate solution, 1 to 1,000, to be renewed three times a day. This reported series of eleven successful cases shows the equally great value of this simpler modified procedure. Only in two of the eleven cases was it necessary to repeat the operation on account of the further spreading of the disease.

Last year Lauenstein proposed, in a paper read before the Medical Society of Hamburg,[3] to improve the Kraske-Riedel method by locating this fence of incisions entirely in the sound tissue, about one inch away from the border of the erysipelas. This should be done to prevent the knife from coming in contact with the infected parts, and avoiding possible infection of yet uninfected tissue. Of course in this case the expression of the serum was omitted. In one of his five cases the scarifications had to be repeated.

This is, in short, the history of the operative treatment of erysipelas. It had been already advised, in 1828, by Dobson,[4] although he failed to describe the procedure in detail.

[1] G. Kühnast: Centralblatt f. Chirurgie, 1886. No. 9, p. 137.
[2] Classen: Centralblatt f. Chirurgie, 1887. No. 19, p. 361.
[3] Deutsche Medicinische Wochenschrift, 1889, No. 11.
[4] Medico-Chirurgical Transactions, 1828, vol. xiv.

My own first experience with this treatment dates from December 12, 1888. A boy, whose knee-joint had been excised by me at the German Hospital, with perfect success, the wound having healed by primary union, returned, with a sinus over the remnant of the outer condyle of the femur, a few months later. The sinus and bone were scraped after application of the Esmarch bandage, and with all the usual antiseptic precautions, and the wound dressed before the elastic band had been removed. But the next morning temperature was 104° F. On examination erysipelas was found around the knee-joint, spreading upward and downward. As the parents refused to have the boy isolated, he was taken home. On the next morning, twenty-four hours after the appearance of the erysipelas, the patient was anæsthetized and the scarifications made, according to the Kraske-Riedel method, around the upper third of the thigh, to which region the disease had already spread. The leg was surrounded, just above the malleoli, by a simple zigzag line of incisions instead of the fence. Irrigation and thorough rubbing of the wounds with sublimate, 1 to 1,000, dressing with clean gauze, soaked with same lotion. On the following morning temperature was down to 99° F., and did not rise again. The erysipelas was permanently arrested.

My second case shows still more evidently that we should not treat erysipelas symptomatically any more, but that we *can* fight it with the knife. On September 16, 1889, I was called by Dr. R. Hein, of this city, to see with him a baby, twenty months old, who, on the morning of the same day had been attacked by a marked erysipelas of the left leg, with all its characteristic symptoms, starting from a perforated varicella pustule. Temperature above 104° F.; restless. As there was no doubt in regard to diagnosis, we met the same evening prepared for the operation. The inflammation meanwhile had spread upward to the knee, and downward nearly to the malleoli. After the usual preparations had been made the child was anæsthetized, and the bloody ring made in an oblique direction around the knee-joint, according to Lauenstein's

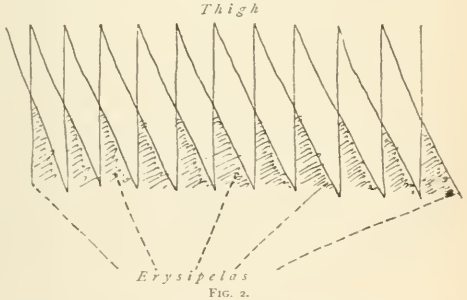

FIG. 2.

modification of the Kraske-Riedel method, in the adjoining sound skin, about an inch and a half removed from the border of the erysipelatous area. As in the first case, the leg was surrounded by a zigzag line of incisions. The next day the erysipelas was found to have proceeded up to the bloody barrier. The whole invaded spot was swollen, red, and hot, covered with blisters, and, as it seemed, painful on pressure. But the erysipelas had not jumped over the fence. Below, it had nearly reached the scarification line. At the knee, where it evidently had spread very quickly, it had entered and filled the sharp angles opening downward of the fence. There the skin was dark-red. But the adjoining rhomboids of skin, outlined by the

incisions, retained the normal white color. The picture was very interesting and demonstrative (Fig. 2).[1] Within thirty-six hours the temperature was normal, and the disease permanently arrested. But two hours later the thermometer again registered 105° F. The cause was found to be an erysipelas of the other leg, where, also, a few open sores had given entrance to the cocci, although they had been carefully dressed all the time. The baby was again put under chloroform and the same operation performed as on the other side. I only put the fence about one-half inch nearer to the border of the infected portion, in order to leave a smaller area of invasion to the threatening foe. Again the wounds were thoroughly rubbed with sublimate solution, 1 to 1,000, and dressed with gauze soaked in the same fluid. The next morning the little patient seemed to feel much better, but was still feverish; temperature, 103° F. The erysipelas had passed the barrier on the anterior aspect of the thigh, and also advanced down upon the foot. The general symptoms being very slight, we observed the child for the next twenty-four hours. But then seeing the red-border line slowly advancing toward the groin, I narcotized the little patient for the third time on the 20th of September, and then scarified the thigh only, anteriorly, according to Riedel, carefully following the superior contour of the redness. The next day the child's temperature was normal, and never rose again. It was cured.

I should like to mention a third very interesting case, although not belonging to my own experience, which occurred at the German Hospital last summer. A man was carried to the hospital in a delirious condition with the diagnosis of typhoid. A careful examination showed an extensive erysipelatous inflammation of the scalp spreading down the forehead. The house-surgeon, D. F. Torek, immediately resorted to scarifications according to the Kraske-Riedel method. The scalp was shaved in its anterior portion, and the ring made under ether, only between the eyebrows they were made somewhat less careful, as these had not been shaved. After-treatment the same as above described. The next morning the delirium had entirely abated, the temperature was down to 101° F., the pulse nearly normal. The cause of the still slight fever was discovered to be the advance of the erysipelas to the right cheek. It had slipped between the eyebrows, where, as I have mentioned, the scarifications had been done less carefully. But the seriousness of the inflammation was broken. On the next day the erysipelas had stopped spreading, and a short time later the patient was all right.

These cases speak for themselves. Others, as Madelung,[2] have had the same satisfactory results. There is no doubt in my mind that this operative treatment of erysipelas is the best and most reliable we know for this disease up to date. It nearly invariably insures success, and is able to arrest the disease permanently at once. It therefore ought to be tried by every physician in a case of erysipelas of the trunk or extremities. In the face the danger of permanent scars that might be left after the scarifications would lead us to limit the method to the most serious cases. But this danger evidently need not interfere with the application of the method to the hairy scalp.

A semi-surgical method, recently advocated by Woelfler,[3] deserves perhaps a passing mention in this connection. He recommends compression of the border region by adhesive plaster-strips. I have no personal experience with this method; but Woelfler claims to have had splendid results. If the same good results should be confirmed by others also in severer cases of erysipelas, and if it should be shown that this method can be applied in any region of the body with an equal success, it of course deserves trial. To avoid the necessity for narcosis in the scarification method, in this small but painful operation, A. Seibert, of New York City, who has recently published an article on the surgical treatment of erysipelas in children,[1] has invented a new instrument, called a scarificator,[2] of the shape of a cone, with which he scratches a large surface with one stroke. He tried it successfully in four cases. Whether the instrument will work satisfactorily in a severe wound of erysipelas, remains yet to be proved. L. Weber proposed a similar instrument for this purpose, in the MEDICAL RECORD, 1889, vol. 35, p. 569. I myself am more in favor of using the knife, which is found in every pocket-case, and of putting the patient under the influence of an anæsthetic. It will be better for the patient and for the doctor. In conclusion I might say this:

1. It seems to be the most rational procedure, in operating for erysipelas according to the Kraske-Riedel method, to make the scarifications near the border, but in sound tissue, as Lauenstein has proposed it.

This dictum is justified by the history of about forty cases, which have so far been published.

2. The barrier is most easily formed, if perpendicular and oblique lines are made alternately.

3. The incisions should not be made too deep, just sufficient to draw blood, as in the rules for vaccination. It is also advisable to narcotize the patient.

4. If after the operation the inflammation continues, nevertheless, its character will be found invariably to have become less serious, from which we may infer that only a relatively small number of infectious cocci have succeeded in crossing the barrier. In strong patients, being in good condition, the operation need not then be repeated. But if the patient is feeble and unfit to cope with a continuance of the disease, new scarifications should be made.

5. The after-treatment must be carried out with moist compresses, soaked in sublimate, 1 to 1,000, to be changed two to three times a day. But unless the change can be made by the doctor, or a competent nurse, the dressings should be left in place and kept moist by frequent irrigation with the same lotion.

[1] Of course the erysipelas will not always stop at the first zigzag line, viz., the one nearest to it, in such a characteristic manner. Frequently it may enter the thomboids. But to spread still farther, it must pass the second zigzag line, which has meanwhile been thoroughly disinfected with the antiseptic. In doing so its strength is again reduced, and is then so weak that it is usually harmless. It is therefore advisable not to content one's self with making a simple zigzag line, but it is always better to add the second one, which will complete the fence.

PROGRESSIVE FACIAL HEMIATROPHY, WITH SOME UNUSUAL SYMPTOMS.[3]

By B. SACHS, M.D.,

PROFESSOR OF DISEASES OF THE MIND AND NERVOUS SYSTEM IN THE NEW YORK POLYCLINIC.

CASES of facial hemiatrophy have an interest apart from their rarity. Any attempt to explain the symptoms necessarily leads up to the question of the existence of trophic nerve-fibres. The unusual symptoms of my case have a special bearing upon this question, and it is for this reason in particular that the case is reported. I am indebted to Dr. A. G. Gerster for the opportunity of seeing this patient. At the time of the first examination she was in Mount Sinai Hospital, and from there was transferred to my department in the Polyclinic. Her history is as follows:

E. K——, Russian, aged nineteen, single; mother died from unknown causes, father living; the patient has one unmarried sister who is also healthy. First menstruation at the age of fifteen years. She was entirely well until about one year ago, when she noticed a peculiar appearance of the skin just below the left nostril, and was also struck with the fact that the face grew thinner below the left eye and above the left angle of the mouth. There is

[1] New York Medical Journal, 1889, p. 430.

[2] Med. Monatsschrift, 1889, p. 664.

[3] The patient was presented to the Neurological Section of the New York Academy of Medicine, December 6, 1889.

no history of any antecedent emotional excitement or injury; no erysipelas or other acute infectious disease preceded the onset of the present trouble.

Examination.—A healthy-looking, robust girl. Right half of face chubby, and all parts well developed. Distinct atrophy of middle and lower third of left side of face; the atrophy involves the skin, fat, and also the muscles and bone of this side of the face. The masseters stand out very prominently, in part as a result of the atrophy of other muscles, and in part because they present one of the unusual symptoms. At intervals of a few seconds only, a series of *clonic and then tonic contractions of the temporal and masseter muscles* can be observed. During this time it is impossible for the patient to open the jaw, and the face wears a very anxious expression. As the spasm extends to the tongue, and sometimes begins with the tongue, speech is impossible while these contractions last. These muscular spasms occur very frequently, and are most apt to follow upon excitement or exposure to cold. They are not only annoying, but painful, and were the cause of the patient's seeking medical advice.

Left side, distance from middle of chin to angle of jaw, 11 ctm.; on right side, 12½ ctm. Left side, from upper margin of naso-labial fold to middle of ear, 10¾ ctm.; on the right side, 11½ ctm.

Movements of face and jaw: Muscles supplied by facial on both sides act normally except on left side, the attempt to puff out cheeks reveals atrophy of the parts and tissues involved.

Action of masseters entirely normal until spasms supervene; lateral movements of lower jaw also of normal extent.

Tongue: Distinct atrophy of left half—another "unusual symptom"—and of left floor of mouth under tongue.

Appearance of skin: No peculiarity except the "scar" on left upper lip, which is slightly pigmented, and which is evidently due to the disappearance of the fatty deposit in the skin; the skin is neither thickened nor glossy; the eyebrows and eyelashes are the same on both sides and entirely normal. No unilateral sweating to be observed even after the administration of a hypodermic injection of pilocarpine.[1]

Tactile pressure and temperature-sense entirely normal. Pain sense diminished a very little on left side.

Taste, smell, and hearing unobjectionable. All these special senses were most carefully tested.

Ocular movements and pupillary reflexes entirely normal. Faradic response of temporal and masseter muscles, of facial nerves and muscles altogether normal; naturally the movements of the right side of face appeared more vigorous.

The examination of the other parts of the body gave negative results, the only point worthy of notice being this, that the repeated thermometrical measurements of external ear showed a difference of one degree in favor of *right* ear.

The history shows that a number of the more serious symptoms observed in other cases—the enophthalmos, the falling out of the hair, and other dermal changes were either but slightly developed or entirely absent. The case was distinguished, however, by the spasms of the temporal and masseter muscles and of the tongue, also by the atrophy of the left half of the tongue and of the floor of the mouth under the tongue.

This exact association of symptoms has been observed in but one other case.[1] Spasms of the masseter and temporal muscles are not mentioned in the many records I have had access to, while atrophy of the tongue seems to be of more frequent occurrence.

The cases of progressive facial hemiatrophy present a great variety of symptoms. Any attempt at a physiological interpretation of the symptoms will reveal the fact that the disease cannot be limited to any one nerve. The old dispute, whether the trigeminus or the sympathetic be the chief sufferer may well be abandoned, for in some cases both are evidently involved; in some the trigeminus only, and in some the sympathetic only. It would be a simple matter, then, to disregard anatomical data and to make facial hemiatrophy a disease of trophic fibres — a true trophoneurosis. In addition to trophic fibres, motor fibres must be involved, or else the unusual symptoms of my case—the motor spasm—could not be explained.

Trophic fibres, like their poor relations, the vasomotor fibres, have been a sort of medical bugaboo. Their existence seemed to be a postulate, yet no one felt able to prove that they were as real as motor fibres are. The physiologists denied their existence, while the pathologists had difficulty in explaining trophic symptoms except on the supposition of the existence of distinct trophic fibres. The trophic symptoms in cases of peripheral neuritis, in compression of the posterior root-fibres by tumors of the cord,[2] pointed indubitably to special trophic fibres in the peripheral nervous system. A little light has been thrown incidentally upon this subject in connection with the study of facial hemiatrophy.

Mendel[3] has been the only one[4] fortunate enough in recent years to obtain an autopsy in a well-defined case of this disease. The patient, who had passed through the hands of Romberg, Remak, Virchow, and others before she came to Mendel, had during more than twenty-five years presented all the symptoms of typical facial hemiatrophy complicated by atrophy of the left upper extremity. Erysipelas during confinement had immediately preceded the first onset of the symptoms. The autopsy, or, rather, the minute examination of the entire nervous system, revealed a neuritis interstitialis proliferans (Virchow) in all branches of the left fifth nerve, most marked, however, in the second branch; the facial was entirely normal, while the left musculo-spiral had undergone the same changes as the left trigeminal nerve.

Apart from some minor changes in the spinal cord (diminution of ganglion cells in the fifth cervical segment), which were secondary to the peripheral trouble, an atrophy of the descending root of the left fifth nerve, and a partial atrophy of the substantia ferruginea deserve most attention.

Mendel very justly claims that, as far as a single autopsy can prove anything, this one would show that the

[1] One-eighth of a grain injected under the skin of the forearm produced slight and general sweating; a higher dosage was not attempted, as the patient was made exceedingly uncomfortable by the above dose.

[3] Neurologisches Centralblatt, 1888, No. 14.

[4] Jolly (Arch. f. Psych., vol. iii.) had an autopsy on a case complicated by multiple sclerosis.

progressive hemiatrophy may be due to a peripheral neuritis (and in this he confirms a suspicion of Virchow), and furthermore it would indicate that the diseased parts, the descending root of the fifth nerve and the substantia ferruginea have trophic functions, presumably in connection with trophic fibres in the peripheral branches of the trigeminus.[1]

Referring once more to my own case, it is evident that the affection involves trophic as well as motor fibres of the trigeminal and hypoglossal nerves. It is a well-known fact that in some toxic cases of multiple neuritis the motor fibres of the peripheral nerves are more affected than the sensory. In some few cases the sensory fibres are involved long in advance of the motor fibres. There is, therefore, nothing foreign in the idea, if trophic fibres exist, that they be the seat of predilection for a disease which would seem to attack the peripheral nerves. My own case would show that this same affection may at times involve the motor as well as the trophic functions (fibres) of these nerves. In this connection it is worth noting that the disease often begins after some acute infectious disease, after erysipelas, and particularly after some traumatic injury to the face. And in these very conditions we recognize the etiological factors most frequent in well-known forms of peripheral neuritis. Lewin, in an excellent article on Hemiatrophy, has proved the traumatic history of 14 out of 68 cases. Mendel finds a peripheral origin in 19 out of 86 cases.

Facial hemiatrophy is evidently not related to the ordinary forms of muscular atrophy which have been the subject of so much discussion during the past years.[2] It would seem to hold kinship rather to other diseases in which the change in the nutrition of subcutaneous, muscular and osseous tissue constitutes the chief feature. Lewin has described cases of hypertrophy of the face and body by way of contrast to these cases of hemiatrophy. Rosenthal has published a case in which the symptoms of facial hemiatrophy were combined with those of a partial scleroderma and alopecia areata, while Schulz, on the other hand, has published a case in which scleroderma was combined with Addison's disease and muscular atrophy. Tuczek [3] has reviewed these cases, together with that of Mendel, and has thus suggested an analogy between them, and it may be worth adding that the symptoms of facial hemiatrophy appear to be exactly the reverse of those which are presented in cases of akromegaly; the symmetrical distribution and the general character of the symptoms in the latter disease, of course, forbidding any further inference as to the relation or differences between the two diseases. At all events, the peripheral nervous system in cases of akromegaly should be thoroughly examined post-mortem.

In conclusion let me repeat that facial hemiatrophy is, in the main, a disease of the trophic nervous system, that the trigeminal and sympathetic nerves are the ones most frequently involved; but that the affection may spread to other cranial and peripheral nerves.

[1] It is very evident that conditions of facial hemiatrophy may be of nuclear origin. Lowenfeld's case (cf. infra) points to this; the case of Flascher (Berl. kl. Wochenschr., 1880, No. 31), which Mills thinks peripheral, is possibly nuclear also.

[2] Mendel's case presented atrophy of the musculo-spiral muscles. In Cartwright's case mention is made of an atrophied spot in the deltoid. "The hole is about one inch in diameter, extending down to the bone, and can be felt through clothing"!

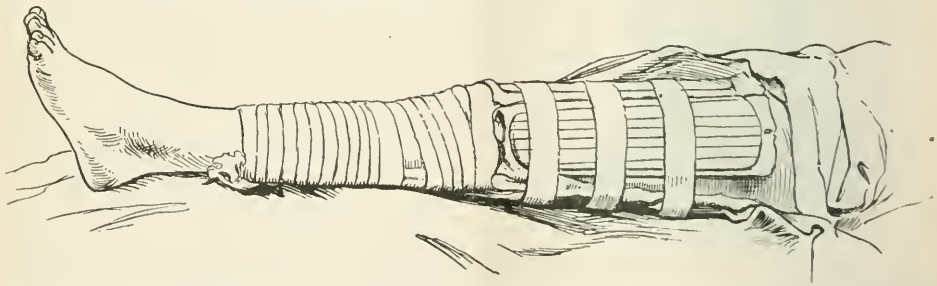
TREATMENT OF FRACTURE OF THE PATELLA.

BY H. H. A. BEACH, M.D.,
SURGEON MASSACHUSETTS GENERAL HOSPITAL.
AND
OTIS K. NEWELL, M.D.,
SURGEON TO OUT-PATIENT DEPARTMENT, MASSACHUSETTS GENERAL HOSPITAL.

THE method of treating fractured patella here described is one with which I have been familiar since I first saw it applied by Dr. Beach at his clinic, seven years ago. I have asked permission to describe it, as I consider it of great value to the general practitioner, because from its simplicity and ready application it is especially adapted to cases in private practice.



I shall not enter into the details of any single case, but describe the apparatus as it is applied, either as adjunctive treatment to the wired compound comminuted patella, or to the simple muscular-action fracture, where, if the case be seen immediately after the accident, the separated edges of the bone may be readily felt beneath the skin.

In the treatment of fractured patella there are chiefly two things to do, and they are to first extend the leg on the thigh, and so control the position of the lower fragment; and, second, to overcome the action of the extensor quadriceps muscle, and thus regulate the position of the upper portion of the bone. Accessory to this should be the pressure by plain roller bandages over the patella, to prevent tilting or "riding" of the fragments.

This is accomplished in the method under consideration by a light wooden ham-splint, well padded and placed posteriorly over the thigh and leg, from the buttock to the upper end of the lower third of the leg, for extension; and by the application of coaptation splints with buckle straps over the extent of the great patella muscle, the quadriceps. A roller bandage should be placed over the coaptation splints, and buckle straps, but is omitted, for clearness of description, in the figure. As for the bandaging over the fragments, this may be prac-

tically confined to simple pressure to prevent "riding," as little can be accomplished with the bone and muscle beneath through the various sorts of traction over the skin. As Hamilton well points out, we should avoid pressing the skin down between the fragments. To relax the rectus femoris muscle, which, as we remember, is the portion of the quadriceps having pelvic origin, the leg should be elevated, and that best, perhaps, by placing pillows underneath and tying them in place with strips of bandage passed around the limb and the bed also, if necessary.

This method is perhaps best distinguished from others by its simplicity and the more direct application of control to the action of the great patella muscle, the contraction of which determines, provided the leg be kept straight, the degree of separation of the fragments. Also by the ease with which the coaptation splints may be tightened by means of the buckle straps about them, and thus steadily prevent the opportunity which diminished swelling and atrophy otherwise furnish the muscle to contract within a loosening apparatus.

The apparatus, after being worn for four or five weeks or more in bed, according to the nature of the case, is then equally suited to movement about on crutches, and from its lightness is especially well suited to this. After a time, four weeks or more, the coaptation splints may be omitted and the ham-splint alone retained. The latter admits, if not too tightly bandaged, of a slight degree of motion, and the first step in overcoming the joint adhesions is thus safely begun. I have had a patient, thus treated after a muscular action fracture, able to walk well without apparatus at the end of nine weeks. A scarcely perceptible fragment separation was present. It is always advised, however, not to attempt too rapid recovery of the knee motion, and to postpone its complete return and unrestricted use even as long as a year.

A FEW CASES OF EPIDEMIC INFLUENZA PRESENTING STRANGE FEATURES.

By WILLIAM F. WRIGHT, M.D.,

NEW YORK.

During the month of January, in common with all the physicians of this city, I saw many cases of epidemic influenza, most of which presented only the ordinary features of the disease. Some, however, gave rise to symptoms so peculiar that I have thought them worthy of note.

One day I was asked to call, with no delay, upon a young woman whose family were well known to me. I found her suffering from severe pain in the uterus and ovaries, attended with a menorrhagia so severe that she and her mother were much alarmed. I was puzzled. My patient was twenty years of age, unmarried, had never had any uterine trouble, and the week before had passed through her usual sickness, in the recurrence of which she had always been perfectly regular. I found she had a temperature of 102° F. Concluding that I had a peculiar form of "la grippe" to deal with, I quieted the fears of the young woman and her mother by assuring them that she would speedily be better.

I gave her at once gr. xv. antipyrine, and ordered every two hours a capsule containing quin. sulph., gr. ij.; ext. belladon., gr. ½; aq. ext. ergotæ, gr. ij.

When I saw her some four hours later she was free from pain, but still had a slight flow, such as during her ordinary menstrual periods. She was, however, suffering from a diarrhœa, which occasioned her considerable alarm, and a feeling of tightness about the chest attended with a spasmodic cough.

I stopped the ergot, but continued the quinine and extract of belladonna, with a mixture of morphia, chloroform, spts. camphor, and arom. spts. ammon., and 10 grains antipyrine every four hours. From this time on the case followed the usual course of the disease. In three days she was perfectly well.

Soon after I was called to see two women, in the last month of pregnancy. Each considered herself in labor, and I so thought. In each uterine pains were well marked, and examination of each revealed the os somewhat dilated. A sanguineous discharge was present, and the head could be felt through the membranes.

While I was wondering how I could attend both, and knowing it was impossible for me to do so, as they lived at a distance from each other, and was trying to decide which had the stronger claim upon my personal services, my attention was drawn to the fact that the woman I then was with had a considerable rise of temperature. Making use of my thermometer I found it recorded 102° F. Giving her xv. grains antipyrine, I returned to the one I had first seen.

During my absence everything had been prepared for the labor I had assured her was already begun. The nurse having arrived, was asserting her autocratic sway, and had many fears to express regarding the future of an eight-months child. In this case I found a temperature of 102° F. also, and gave xv. grains of antipyrine. There were no more symptoms of labor in either case.

Each passed through the usual course of influenza, recovered entirely on the third day, and, a month later, at the expiration of the full term of pregnancy. I delivered both of healthy children.

The same day I was called to see two gentlemen, one a prominent artist, nearly seventy years of age, whom I found with a temperature of 103° F., attended with pain in different parts of the body, and with, what annoyed him most, a feeling of soreness along the urethra and pain in one testicle, which had already begun to swell. There was also a slight urethral discharge, such as is seen with alkaline urine. His urine was normal. Under what had become with me quite a routine treatment of "la grippe" he improved rapidly. The soreness of, and discharge from, the urethra disappeared in a few hours. But the testicle remained swollen and painful for several days. The other gentleman was a well-known public lecturer. It was late at night when I reached him. I found him sitting on the edge of his bed suffering from a dyspnœa which alarmed not only himself but his friends, who in their efforts to relieve him had well irritated his neck and chest with mustard. He also had the usual rise of temperature of 102° F. No symptom other than the sudden attack of dyspnœa had attracted his attention. Under a single dose of antipyrine, with full doses of belladonna and spirits of camphor, repeated every two hours, his dyspnœa disappeared entirely. The following day he felt quite well, but his voice was gone, a matter of much importance to him, as he had an engagement to speak that evening. Under energetic treatment, carried out through the day, he was able to appear that evening and speak with his usual strength of voice. There was never any return of the dyspnœa.

I also saw some cases in which irritability of the bladder was the most prominent symptom; others in which a gastro-enteritis alone attracted attention. In the case of an old lady, in whose family three were sick at the time with the prevailing epidemic, a sudden attack of heart-failure, attended with no other symptom, and from which she fully recovered, although ninety years of age, may have been due to the active cause of the epidemic, although I thought not.

55 West Tenth Street.

Enforcing the Notification of Disease.—The town council of South Bethlehem, Pa., recently notified the physicians in the place that unless they reported promptly all cases of contagious disease the statutory fine of $30 for every case would be rigidly enforced. This action was due to the fact that several cases of scarlet fever, which had not been reported, had come to the notice of the health authorities, who made complaint to the council.

Progress of Medical Science.

Idiopathic Pericystitis.—Dr. Joseph Englisch, of the Rudolf Hospital in Vienna, says the cavum præperitoneale Retzii is the space into which the bladder ascends as it fills. Opinion differs as to the constitution of its wall. Some think that the lower portion of the straight abdominal muscles at the back are without a special covering, and that the ascending bladder comes into immediate contact with the muscles; others assert that this part of the muscle has also a sheath. The latter view is held by Englisch. The diseases of the cavum peritoneale Retzii are chiefly of an inflammatory nature, being either acute or chronic. Englisch classifies them thus: 1. Idiopathic, when no cause can be assigned, though infection may be possible. 2. Traumatic, the result of external injury. 3. Metastatic, after infectious diseases of other organs. 4. Consecutive, being the development of diseases of adjacent organs. Englisch finds records of only 23 cases of idiopathic inflammation, 18 being cases of males. The age at which this disease mostly occurs seems to lie between eight and thirty. He inclines to the opinion that an existing tuberculous constitution or habit predisposes to inflammation of the cellular tissue in the neighborhood of the bladder. Any disease of the urinary organs especially predisposes to inflammation. He agrees with Leufser in distinguishing two stages of the disease, viz., general symptoms and the tumor. The symptoms of the first stage are pain, sickness, uneasiness, loss of appetite, vomiting, and constipation. The tumor may be observed already on the second day, or only after some months. It develops from below upward, and may reach the height of the navel. It may be sharply defined or not, and in the former case it may be symmetrical or unsymmetrical with the median line. The symmetrical tumor assumes the shape of the filled bladder, but generally the tumor is unsymmetrical. Bimanual examination best determines the shape. The consistency of the tumor is at first doughy, and later on hard, and when suppuration begins there is partial softening. The surface is lumpy as long as the abdominal wall remains intact. A peculiar feature is that no decrease (or only a very slight one) of the tumor is caused by catheterism. Examination from the rectum is indispensable. The passing of urine is but little interfered with, and may even be normal; in only a few cases is there ischuria. The urine itself is normal, or undergoes little change, at any rate at the commencement of the disease. In every case, except one, fever set in, generally together with the first symptoms, but sometimes sooner, sometimes later. There may or may not be collapse. The tumor burst in 6 of the 23 cases, became hardened in 2 cases, and showed suppuration in 15 cases. Hardening in the neighborhood of the ureter causes engorgement of the kidneys. The pus usually discharges outward, but possibly into the rectum, vagina, urethra, peritoneal cavity, or other places, *e.g.*, the front of the thigh.

Idiopathic inflammation of the cavum Retzii may be mistaken for peritonitis, enteralgia, cystitis, local peritonitis, retentio urinæ, calculus vesicæ, extra uterine pregnancy, neoplasms, adhesion of the bladder, and inflammation of the abdominal muscles. Englisch then goes into the differential diagnosis.

The prognosis is favorable; in only 3 cases death occurred through perforation. The treatment is symptomatic: application of cold, later of moist warmth, rubbing with unguentum hydrargyri, unguentum iodatum; in case of suppuration, opening of the tumor, with the incision as in sectio alta; and in spontaneous discharge, proper antiseptic treatment.

Englisch divides traumatic inflammation into two groups, the first of which comprises those affections of the cavum Retzii which occur only through extravasation of blood in consequence of an external injury; the second group comprises the genuine traumatic inflammations of the cellular tissue. Of the first group he has found records of but 5 cases, of the second only 8 cases. In the first group there were 3 deaths, and in the second 1 death.

Of metastatic inflammation only 3 cases were observed, all occurring after typhoid fever. In all 3 cases the symptoms of inflammation of the cellular tissue of the cavum Retzii appeared only in the second period of the fever. One case recovered with suppuration, another without suppuration, and in the third case death occurred through perforation into the abdominal cavity.

Consecutive inflammation is the most common form. It originates in diseases of the urinary organs, of the genital organs, and of the other organs of the wall of the pelvis. The worst cases observed were those which occurred after gonorrhœa. In consecutive inflammation the urinary difficulties are more considerable than in other forms of inflammation. Englisch says: "It seems perfectly allowable to assume that there is some agent that can affect the cellular tissue of the cavum Retzii alone, and produces the circumscribed form of inflammation of the cellular tissue. If the agent affects the bladder, at the same time there occur those complications that are connected with inflammation of the bladder, the degree of which is determined by the extent to which the mucous membrane of the bladder is affected. Of what nature this agent is cannot be determined as yet, but the process agrees with that observed in other infectious diseases. We have, therefore, to deal here with an infectious disease, as Leufser has already indicated." In conclusion, Englisch gives eleven cases out of his own practice, and tables of the other cases recorded in the literature of the subject.—*The London Medical Recorder*, January 20, 1890.

The Bacteriology of Whooping-Cough.—At the third general meeting of Russian Medical Men at St. Petersburg, Professor Afanasieff read an able and exhaustive bacteriological essay on the subject of pertussis. A summary of this author's conclusions has already appeared in these columns. At the suggestion of Professor Afanasieff, who was anxious to verify his results, Dr. Semtchenko took up the line to further investigate the matter, especially in clinical regards. The conclusions arrived at by the Kazan pædiatrist may be given thus: 1. Afanasieff's bacterium is actually specific and, hence, fully entitled to bear the name of the bacillus tussis convulsivæ. 2. The micro-organism makes its appearance in the sputum during the catarrhal stage, somewhere about the fourth day of the disease, but possibly still earlier. 3. Subsequently its numerical strength increases, the intensity of paroxysms keeping pace with the increase. 4. The microbes disappear from the discharge, apparently somewhat before a complete cessation of whoops (about the time when the number of paroxysms sinks down to four or two per day). 5. As soon as pertussis becomes complicated with catarrhal pneumonia the bacilli in the patient's sputa show an enormous increase in number. 6. Altogether the pertussis pneumonia seems to be quite different from other varieties of pulmonary inflammation. 7. The bacillus tussis convulsivæ presents a great importance not only in etiological and diagnostic, but also in prognostic regards. 8. As to the behavior of the microbe toward antiseptic agents, its vitality is destroyed as soon as the medium (jelly) contains corrosive sublimate in the proportion of 1 to 60,000, or resorcin in that of 1 to 1,200, or phenol in the same one, or hydrochlorate of quinine in that of 1 to 800. Drs. Afanasieff's and Semtchenko's researches were repeated (at least partially) by Professor Tschamer (*Wiener med. Wochensch.*, No. 17, 1888) and Dr. E. C. Wendt, of New York (*Medical News*, June 2, 1888). On the whole, both of the authors confirmed the statements made by the Russian observers. Dr. Wendt, however, differs from Dr. Semtchenko in some more or less subordinate points. Thus, he could not detect the presence of the bacilli in earlier stages of

the affection; neither was he able to notice any co-relation between the number of paroxysms and that of the bacteria in the patient's sputa; while, on the other hand, he found still the bacilli in the discharge, even after a complete disappearance of whoops. In conclusion, Professor Afanasieff draws attention to the several points which demand further elaborate investigations. It is necessary, he says—1, to more closely examine the distribution of the microbes in the respiratory mucous membrane, as well as in bronchopneumonic foci; 2, to study the behavior of the bacterium toward various coloring matters (in order to discover a characteristic differential test for the bacillus); 3, to study the spore-formation (which is important, especially in prophylactic regards); 4, to most carefully inquire into a clinical bacteriology of the pertussis sputa, from the beginning to the end of the attack, and even during convalescence (which is important for diagnostic, prognostic, and prophylactic purposes); and 5, to further study the behavior of the bacillus toward all possible parasiticide agents (to possibly discover some specific bactericidal substances, which discovery would prove of untold value in regard to the therapeutics of the infantile scourge in question).—*The London Medical Recorder.*

Practical Points in the Performance of Nephrolithotomy.—At the conclusion of a recent address on the subject of Nephrolithotomy (*The British Medical Journal*, January 18, 1890), Dr. Jacobson gives these directions: I. To count the ribs. That this is not an unimportant detail is proved by the fact that Professor Dumreicher, of Vienna, accidentally opened the pleural cavity in an attempt to remove a pyelonephrotic calculous kidney. Post mortem, the last rib was found to be rudimentary, and the pleura projected a good deal below the lower edge of the eleventh rib. II. To make a sufficiently free incision, especially in a stout patient, and a deep loin. Additional room may be gained by converting the usual lumbar incision into a **T**-shaped one, or by making use of Konig's incision, in which the muscles are cut through as far as the rectus, and the peritoneum pushed forward. A small stone in a kidney will always be liable to be overlooked, but a surgeon does not give his patient or himself a fair chance who is content with exposing the kidney through a limited incision, and then trusting to punctures with a needle. III. To pack away with sponges the colon, which is often troublesomely distended with flatus in these cases. IV. If the stone cannot be felt either in the pelvis or after palpation of the posterior and anterior surfaces of the kidney, this should be drawn up and out of the wound as far as possible, and again examined, a careful watch being kept upon the pulse. V. In puncturing the kidney, to try, as far as possible, to open the calyces systematically. VI. If palpation and acupuncture fail to find a stone, the kidney should be carefully opened and sounded. I will recur to the subject of hemorrhage shortly, and take first the best site of opening the kidney. Hitherto, in five doubtful cases, I have incised near the pelvis, as the viscus is thinner here, and as the surgeon can better reach the calyces. Mr. Jordan Lloyd, however, recommends the following method of exploring the interior of a normal kidney: "When the kidney is exposed through a lumbar wound I puncture its lower end with a long-bladed tenotome in a direction upward and inward, making for the lowest of the calyces. If the surgeon is observant and his knife is keen he will readily appreciate the moment when a cavity is struck by the altered resistance offered to the puncturing instrument. . . . It is important, because a tenotome may be pushed up to its handle in a normal kidney without tapping its interior cavity, having travelled along the kidney substance rather than through it. Into this opening I pass a child's bladder sound, and systematically explore the whole of the pelvis." It is advised that the blade should be not more than one-third of an inch in length, a stem of about seven inches, and the size of a No. 3 English catheter. It should be passed at once to the top of the kidney cavity, a distance of nearly four inches, and the exploration should be carried out systematically from above downward, the point being rotated in all directions, so as to investigate both tubes and calyces as the instrument is withdrawn. In this manner Mr. Jordan Lloyd has succeeded in finding a calculus, after needling and palpation had been assiduously tried with negative results. VII. Hemorrhage from an incision into the kidney is certainly arrested by firm, careful plugging with strips of sal alembroth gauze. On the five occasions on which I have used this plan I have removed the strips the next day with the aid of a few minutes' anæsthetic, gas sufficing for this. It is said that this plugging may cause vomiting. This did not occur in any of my cases. It ceases on the removal of the plugs. Care must be taken that the plugging is thoroughly done. If inadequate it will have to be repeated in a few hours—perhaps more than once—thus leading to exhaustion and setting up cellulitis, which may of itself be fatal, owing to the important relations of the kidney. VIII. Sources of difficulty in removing the stone. The chief of these are: 1. A very mobile kidney, which gets away deep in the wound; 2, a stone situated on the anterior surface and near the entrance of the vessels; 3, a small stone in a sacculated kidney, the stone falling into one of the sacculi, and thus being hard to find. IX. Multiple calculus in a suppurating, damaged kidney. If the question of nephrectomy arise this step should, as a rule, be deferred, and the kidney thoroughly drained, for the following reasons: 1. Additional shock and loss of blood will be avoided. 2. The condition of the opposite kidney, very possibly calculous also, will be made clearer by waiting. 3. The bulk of the kidney will be lessened by drainage. 4. Though a source of discomfort (if an open sinus persist) it may still do some and important work. X. If the kidney has been much disturbed it should be stitched *in situ*.

The Surgeon and Sentiment.—Under this caption the *Boston Medical and Surgical Journal* recently discussed the ideal surgeon of the laity, with the surgeon of reality, as evinced through professional and private life. The *Journal* assumes that the former is: "A man of given determination without any of those delicate refinements which might lead him to drop the tear of pity over the sorrows of the trembling victims of his scientific power. Stern judgment should belong to him as much as valor to the soldier, justice to the jurist, or sensitiveness to the poet. As the warrior revels in warfare, the lawyer in litigation, the clergyman in theology, so the surgeon should rejoice in bloody, physical calamity; it should be the breath of his nostrils, his reason for existence." As a matter of fact, we believe, says *The Medical Age*, these ideas are confined chiefly to the vulgar, and even among such, are held in the main toward those members of the profession who are most charlatanistic and ignorant. We recall three so-called surgeons who perfectly fulfilled this ideal: one whose medical knowledge was obtained solely as a hospital steward in the regular army; one a man of mediocre medical education, by nature cruel, and who really delighted in the knife and in the sight of blood, and subsequently ended his days in an asylum; the third very like the preceding, and who, though oft boasting his nerve, and delight in operating, ultimately took his own life rather than submit to the knife that would have relieved him of an otherwise incurable malady.

The Doctor as a Dramatist.—A dramatic poem called "The Miser," written by Dr. S. Weir Mitchell, was recently successfully produced in Philadelphia. Dr. Mitchell has proved that a man may possess fine poetic and literary talent, and at the same time have a logical and scientific mind. We congratulate him upon his latest success; but hope sometime he may turn his talents to more cheerful themes than avarice, Satan, and death.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, March 15, 1890.

TERTIARY SYPHILIS.

AN important contribution to the subject of the cause and frequency of tertiary syphilis was made in a discussion on this subject before the International Congress of Dermatology and Syphilis, held at Paris last summer. The presence of Neumann, Mauriac, Fournier, Leloir, and others gave especial authority and weight to the opinions expressed.

Professor Neumann stated that the efficient causes for producing tertiary syphilis were: 1, Insufficiency of treatment; 2, constitutional vices, such as tuberculosis; 3, all the causes of impaired nutrition.

Mauriac stated that tertiary syphilis occurred in ten to twenty per cent. of cases, and less often in those not treated. The most frequent time of the appearance of the third stage symptoms was between the third and sixth year.

The most frequent tertiary accidents were those affecting the skin and mucous membranes; after this came syphilis of the nervous system. Other forms of visceral syphilis were much more rare.

M. Fournier based his very positive views upon a statistical study of two thousand six hundred cases observed in the city of Paris.

He states that the frequency of tertiary syphilis increases up to the third year, when it reaches its greatest height. From the fourth to the eleventh year it declines rapidly in frequency, and then more slowly, ceasing practically after the thirtieth year. Indeed, between the twenty-first and thirty-first year it is very rare. Fournier states, contrary to the usual opinion, that the nervous centres are more often affected than any other organic system. His figures are 1,085 cases of nervous syphilis, as against 787 cutaneous, and 612 mucous syphilides. Among 3,429 cases, there were 1,085, or about one-third, in which the nervous system was affected. Assuming that ten per cent. of all persons who contract syphilis develop tertiary symptoms, it follows that three or four per cent. of all who contract syphilis will suffer from complications affecting the nervous system. The brain is most often affected, and after this come degenerative affections of the spinal cord, such as locomotor ataxia

Dr. Haslund, of Copenhagen, agreed essentially with the other speakers as to the causes which are effective in leading to tertiary syphilis. He placed stress, however, upon alcoholism and malarial infection, and intolerance of the patient to the use of mercury.

Dr Vajda, of Vienna, stated that among 632 tertiaries, sixty-two per cent. had had no previous treatment, while thirty-eight per cent. had had mercurial treatment. The cases treated, also, were affected less severely. All the cases of tertiary syphilis suffered in their general nutrition, and weighed on an average ten kilograms less than healthy adults of their age and height.

The contributors to the discussion based their views largely upon hospital experience; and they failed to bring out one cause well recognized here, viz., that excessive mental strain tends to produce tertiary syphilis of the brain.

The facts contributed show, apparently, that syphilis of the nervous centres is more common than has been supposed, and very likely much more so than it used to be.

THE MIRROR SYSTEM IN INSANE ASYLUMS.

WAR rages between Norristown, Pa., and Utica, N. Y., or, to be more exact, between the gentlemen conducting the insane asylums of those respective towns. It seems that Dr. G. Alder Blumer, of Utica, not long ago published the following discovery and indictment in the *American Journal of Insanity*:

"At the State Asylum for the Insane at Norristown a system of reflecting mirrors for the constant observation of the wards has been adopted. An inspector is to be stationed in a small room in the attic, and, by an arrangement of mirrors and shafts, can have in view all of the building occupied by patients. While this scheme reflects credit upon our American ingenuity in adapting means to ends, it is scarcely creditable that in this age and generation such a system of espionage should be necessary in a civilized State like Pennsylvania. Can it be possible that honest and efficient supervisorship cannot be bought there for love or money? Must we have the methods of a Russian prison in an American hospital? Oh, shame upon us! It will be interesting to watch the outcome of this novel experiment as it affects the patients in the genesis of delusion."

To this Dr. Chase, of Norristown, replies in an open letter of denial, explanation, and defence. "It is true," he says, "that there is a system of supervision of the attendants and patients by ward inspectors. These are placed, not in an attic, but in the division wall, between the two wards of the second story. A communication has been established between the two stories; by the use of a tube and an arrangement of mirrors a comprehensive view of the wards below is obtained."

Dr. Chase asserts that his system has worked well, and has been warmly approved by those who have examined it, and he returns a declamatory Roland for Dr. Blumer's rhetorical Oliver. "Do not," he says, "the many abuses and accidents, not to speak of homicide, that have occurred at Utica, even since your advent, bear me out in my statement. 'Oh, shame upon us!' sure enough! . . . Men whose lives are passed in narrow confines often forget that the great world moves. It is difficult, they say, to surmount prejudice, to look, as it were, over asylum walls, especially if they be faced and capped with huge Corinthian pillars. But, as the oarsman says, 'Break away, break away, my boy!' from the rocks—the inflexible 'propositions'—on which your illustrious predecessor rested so long in shallow water."

We trust no hard feeling will be engendered at Norristown and Utica. Both have excellent asylums, but it must be admitted that the former place is more progressive, and we shall look for the gradual adoption of the mirror system at Utica.

STERILITAS VIRILIS.

Much attention has been paid, of late, to man as the factor in sterility. Usually if a married couple continue childless the fault is laid on the woman, and, as a rule, no doubt, this is correct. But abundant evidence has been obtained to show that man, who is not impotent in the sense of being able to have coitus, is yet the sterile one.

Dr. L. Casper, in a recent article read before the Berlin Society for Internal Medicine, discusses this subject in an interesting manner. There are, he says, two forms of sterilitas virilis, viz., aspermatism and azoöspermia.

To the former class belong those cases in which, though there is connection, there is no emission of semen. This may be due to—1, defect or closure of the ductus ejaculatorius; 2, inexcitability of the ejaculation centre; 3, loss of skin sensibility of the penis; 4, psychical influences.

Interference with the patency of the ductus ejaculatorius is caused by its obliteration or deviation posteriorly, urethral strictures, and phimosis. The second form, called atonic aspermatism, is due usually to excessive masturbation. The other forms are very rare.

Azoöspermia exists in conditions of cachexia and in absence or disease of the testicles. Casper believes that it is not very rare in tertiary syphilis, even when there is no local lesion of the generative organs. He cites the statistics of Liegois and Bryson, who, among twenty-one cases found azoöspermia five times.

The term "sterilitas virilis" is understood not to include impotence, but only those cases in which connection is still possible. It is evident, however, that Casper has not included all its forms. There is a third, known as misemission, which is characterized by a failure to deposit spermatozoa in the upper part of the vaginal tract.

This last form results from hypospadias and other deformities of the penis, or from inflammations or fistulous openings in the canal.

The treatment of sterilitas virilis necessarily varies greatly. Surgical procedures are usually indicated in aspermatism, while anti-syphilitic or tonic treatment is indicated in azoöspermia. In the anæsthetic form, Curling reports a case relieved by the local application of a certain cantharidis to the gland. In misemission, aside from surgical measures, "homoculture" by means of a syringe has been tried, somewhat disastrously. Of late, however, it has been recommended again.

THE BOGUS RUTLAND MEDICAL COLLEGE.

The recent decision of Judge Powers, of Vermont, denying that the so-called Rutland Medical College had authority to confer diplomas, brought up some interesting legal questions. The case was the result of the petition of Mary J. Townsend, of Rutland, for a mandamus to compel the censors of the Vermont State Eclectic Medical Society to give her a certificate for the practice of medicine in this State, under the diploma granted her by the Vermont Medical College of Rutland.

There is a general law in Vermont providing for the organization of corporations by voluntary association, for the purpose of establishing and maintaining "scientific, charitable, and benevolent institutions and such societies as have for their object the promotion of moral, intellectual, and spiritual development." The practical question was whether that statute was broad enough to cover the organization of a medical college, with full authority to issue diplomas.

In his decision Judge Powers decided that it was not.

The facts were that a certain Dr. Dutton, of Boston, and his wife, had taken advantage of this law and had organized a so-called college. No systematic instruction was given, however, and the institution was nothing but a diploma mill, pure and simple.

Fortunately, its activity was promptly and completely destroyed before much harm was done. We think that the medical profession of Vermont is entitled to much credit for having so quickly stamped out this pernicious organization.

THE NEGLECT OF ANATOMY IN THE SCHOOLS.

The examiner in anatomy of the North Carolina Board of Medical Examiners gives some striking facts with regard to the incomplete knowledge of this branch on the part of the applicants for medical degrees. In the past three years, 1887–88–89, there have been 147 persons who have applied for a license to practise medicine in North Carolina. Of these 106 succeeded, 41 failed. But of the whole number, 98, or about two-thirds, failed to answer seventy per cent. of the questions in anatomy.

The examiner in anatomy naturally deplores the fact that there is such a deficiency in this fundamental branch of medical knowledge, and he publishes the examination papers, which show that the questions asked were not severe or unreasonable.

It is quite possible that, with the large increase in the technicalities of medicine, there is now less relative stress laid upon a thorough knowledge of anatomy. The wide adoption of a progressive course of study by which students finish and lay aside anatomy in two years, is not without its evils. Two years' study is not long enough to fix anatomy firmly in the mind, and, at the end of the third or fourth year, the student graduates with much of it forgotten.

The Examining Board of North Carolina has done a service in calling attention to this apparent neglect of anatomy in our medical colleges.

RHINOLOGY AND OTOLOGY.

For some reason it has heretofore been the rule that the ophthalmologist should be the otologist, and that the care of the eye and the ear should go together. Whether this custom has been based upon chance, alliteration, physiological analogies, or anatomical propinquity we do not know; but it is certainly not a good one. Pathologically the ear and the nose and the throat are most closely united, and it is the laryngologist and rhinologist who should master ear diseases rather than the ophthalmologist. Dr. W. H. Daly, in a recent paper read before the Section on Laryngology, on the relation of naso-

pharyngeal disorders to deafness, puts the matter a little differently, for he asserts that the otologist ought to be a rhinologist, or what now seems to be the fashionable thing, an intra-nasal surgeon. He states with much positiveness that the modern otologist neglects the nose, or is incapable of properly treating it. Dr. Daly further affirmed that eighty per cent. of aural troubles were due to naso-pharyngeal disorders, while Dr. Bosworth put the percentage as high as ninety-five.

Dr. Roosa and Dr. Pomeroy, in the discussion of Dr. Daly's paper, vigorously repelled the insinuations made against the alleged intra-nasal agnosticism of the otologists, and cases were cited in which ear disease was produced by the excessive boring, sawing and burning of the nasal cavities by the rhinologist.

There was practical unanimity, however, on the point that rhinologists and otologists should work together, and perhaps this may be better than to have, as is proposed by some, the otological lamb swallowed by the rhinological lion.

A NEW USE FOR THE PHONOGRAPH IN MEDICINE.

When Edison's phonograph was first presented to the public in its improved form, it was thought that it might be turned to practical use in the teaching of physical diagnosis, but this has been found impractical, since it is not possible, without great trouble and the use of accessory apparatus to record the faint cardiac and respiratory sounds. Dr. Litchwitz, of Bordeaux, has suggested another use for the instrument, which would seem to be entirely practical and of real value. He proposes to employ it in otological examinations as a measure of the hearing power. It possesses the advantage over the crude method of listening to the ticking of a watch, that the element of unconscious deception can be entirely eliminated. The intensity of sound can be graduated to a nicety on different parts of the cylinder, and thus a definite scale may be made which will equal in its exactness and universality of application the visual tests employed by oculists the world over. It will be possible also to measure the degree of hearing in one ear without the confusion resulting from the sound being heard in the well ear, as may happen when the watch is employed.

A GOOD WORK FOR THE WEALTHY.

A charitable Englishman, whose name is not published, but who is said to be the Duke of Westminster, has just given half a million dollars for the establishment of a convalescent home for the poor of London. In this age of hospitals and dispensaries, when there are really more than there is any use for in most of the large cities, no more useful charity could be devised than this. The hospital, oftentimes, will not keep a patient who has recovered from a serious illness until his health is fully established and he is able to go to work again, yet the sending him back to his home exposes him to a relapse or some other trouble, and may cause the loss of a valuable life which a few more days of nursing might have saved. Why cannot some charitably disposed person here, who may be contemplating the foundation of a new hospital, or the rich endowment of one already in existence, be induced to dispose of his gift in some such way as this, and place his money where it will be of the greatest benefit to the poor whom he wishes to relieve? There is a convalescent home in this city; but as it has accommodations for a comparatively small number, and restricts its benefits to Protestants in religion, it can be understood that there is still room for another institution of the kind which will accommodate more and place no religious restrictions on its admissions.

AMERICAN DIPLOMAS ABROAD.

The following item has excited very wide attention. It contains a piece of alleged news cabled from Berlin:

"The two hundred American physicians matriculated at the University of Berlin are greatly agitated over the refusal of the German authorities to recognize their American diplomas, in the recently issued University calendar. While the medical degrees of all other nations are duly recorded, those conferred by institutions in the United States are entirely ignored. In explanation of the omission, a high official attached to the ministry of education to-day said: 'Your American colleges don't come up to our German standards, by any means, and are too various and miscellaneous in their character to claim recognition.' American physicians here are never addressed by their title, nor are their letters so inscribed, although there are in Berlin graduates of several of the leading American medical colleges." The telegram then goes on to say that "it is proposed by the ignored medicos to prepare a memorial to the authorities expressive of their astonishment and indignation at the treatment received."

There is evidently a great deal of exaggeration in the above statements. In the first place, there are not, and never have been, two hundred American physicians matriculated at the University of Berlin; and the further declaration that American physicians are never addressed by their title is absurd.

There are exaggerated ideas abroad, no doubt, as to the cheapness of American medical diplomas. The facts are that about one-half the three thousand five hundred doctors annually graduated in this country go out from large and well-equipped colleges in New York, Massachusetts, Pennsylvania, and the West. These men have studied well under good conditions, and deserve recognition as members of a learned profession.

It would be most unjust for foreign universities to condemn American medical diplomas as a whole, and it would be particularly impolitic for the Berlin University to do so just when efforts are being made to have a great International Congress under the auspices of the medical profession of Berlin.

CONGENITAL SMALLNESS OF THE ARTERIES.

One of the most wonderful processes of the human body is that by which each part is formed and moulded so as to occupy its proper place and space in the organism. In order to perfect health and usefulness of the whole, each part must bear its due relations and proportions to each other part, not absolutely or rigidly, but within certain narrow limits. If an important organ is insufficiently developed serious consequences generally result.

Cases are frequently observed *post mortem* in which the arterial system has not been developed in size to the extent which is proportional to the growth of the other organs. The question of interest to the practitioner is: What are the clinical phenomena which attend such a deformity? Virchow has declared that, in the case of girls, such deformity is frequently connected with chlorosis. But the same deformity is just as likely to affect men as women, yet men are very rarely, if ever, chlorotic. What, then, is the life-history and what are the disease-conditions of the men in whom this abnormality exists? This is a question which has as yet received but little attention. It is probable that the instances of this complaint are generally classified under the title of "organic disease of the heart" (although the heart is only secondarily affected), or of "kidney disease" (although the disease of the kidney is most likely only a consequence of the other).

Very interesting articles upon this subject have been published by Fraentzel (*Deutsche Med. Woch.*, July 19, 1888, p. 589), and more recently by Hanford (*Practitioner*, November, 1889), p. 321, on which the present remarks are based. Observation seems to show that children of both sexes may have arterial systems too small for their bodies. In some this results from tardy development of these parts and is not permanent, the arteries growing to a proper size after puberty. In others it is permanent, the arteries remaining throughout life too small for the body.

If the disproportion is very great, the patient is pale and weak from infancy; if it is only moderate, the patient will pass through infancy and childhood without marked symptoms, the heart having become sufficiently hypertrophied to counterbalance the narrowness of the arteries. When, however, the toil of active life begins, the deformity gradually makes itself felt. The heart is no longer equal to its unequal task, and its cavities become dilated and its walls weakened, the natural consequences of these changes ensuing.

The results of the deformity are, naturally, most serious in men who have severe labor to perform, while in women who do not exert themselves much, simple lassitude and debility are observed—they are chlorotic, the hypertrophy of the heart enabling that organ to meet ordinary demands upon it, but not being sufficient for any prolonged strain.

Fraentzel relates several cases in which grave disorder of the heart and inability to work resulted from this smallness of the arterial system, the patients being all of the male sex. In two of the cases the condition was made certain *post mortem*, in the others the diagnosis rested upon symptoms only. The history of the disease is about as follows: A young man, well built and without perceptible disorder of the heart, except, perhaps, occasional palpitation, and with no history of rheumatism or other serious disease, is examined for entrance to the army, and admitted as a healthy man. Soon, however, he falls into a general decline, being unable to endure protracted exertion. An examination now reveals incipient dilatation of a hypertrophied heart. The radial arteries are abnormally small and cordy, and the carotids and arteries of the limbs are small and tense. The heart-sounds are quite normal, excepting a slight increase in intensity of the second sound. The urine is clear, without sediment, and free from albumin. The patient is greatly improved by rest in bed, the strength returning, and the dilatation of the heart becoming less marked.

He now resumes his former labors, and for a time feels well. Soon the old trouble recurs with greater severity, and he returns to hospital with dilatation of the heart, dyspnœa, palpitations, œdema of the lower limbs, and dropsy of the lungs and pleura. The liver is greatly congested, and the urine exhibits slight quantities of albumin. The heart-valves still act normally. After gradual increase of all the symptoms death takes place.

Post mortem the valves are found to be normal, the coronary arteries unchanged. The heart is hypertrophied, and the ventricles are greatly dilated. The aorta is very small, so that it will hardly admit the little finger, and all of the other arteries are likewise small and thin-walled, the vessels nearest the heart exhibiting signs of degeneration (apparently from overstrain). The other organs are unaffected, save as a natural result of the diseased condition of the heart and arteries.

Fraentzel recalls two cases in which he made a diagnosis of disease of the heart from sudden overstrain; but, as the patients denied that they had been subjected to any sudden unusual strain, he would, in the light of his present knowledge, consider them as instances of the disease now under discussion. His experience with still other cases would lead one to believe that, if discovered in time and treated by prolonged rest, these conditions would not forbid the pursuit of a quiet profession in after-life.

One similar case, with autopsy, is related by Dr. Hanford.

The diagnosis of the disease under consideration rests on the hypertrophy of the heart, the smallness and tenseness of the arteries, the absence of history of sudden strain, the healthy condition of the heart-valves, the freedom of the kidneys from organic disease, and the peculiar history of the affection, as already given.

The treatment of most importance is absolute rest and a quiet after-life; other agents being employed according to the needs of each individual case.

THE MEDICAL PROFESSION OF TEXAS.

The wane of the medical profession of Texas is announced. In his presidential address, Dr. F. W. Johns, in resigning the chair at the last meeting of the West Texas District Medical Association, said:

"But if I read correctly the signs of the times, the strength and patronage, the power and influence of the regular profession of medicine among the people is on the wane; and should we fail to stand shoulder to shoulder—county, district, State, and nation—in the correction of the adverse conditions, the dissolution and downfall of your beloved organization is, at least, probable."

The editor of *Daniel's Texas Medical Journal* comments upon these words in a very serious spirit.

"For years," he says, "the Texas State Medical Association has petitioned the Texas Legislature, through committees of her ablest men, to enact a law to restrict the indiscriminate practice of medicine. In vain was it repeatedly pointed out that a large majority of the States of the Union had taken such steps; in vain were decisions of courts cited, declaring the constitutionality of

such laws and the competency of States to regulate the practice of medicine by statutory enactment. Every argument was exhausted in the endeavor to get even a modicum of justice in the way of such legislation."

The conclusion is that the profession of the State has never commanded the respect of the public, on account of the lack of character, ability, and sound education in a great number of its members.

We heartily sympathize in the hope expressed by our contemporary, that the fight for progress and reform be kept up; and we especially urge the continuance of the demand for an efficient State Board of Health, a Board of Medical Examiners, and a regulation of medical practice. The enactment of the desired laws has failed ignominiously in the past, but this should be no discouragement. Perhaps the Texas doctors have not quite learned the technique of getting their bills through a legislative body; let them study this, and not rely upon the justice of their case alone. For good wine needs a bush nowadays, particularly in the political arena. Texas is a great State and has many courageous and able men among the profession; let them keep up the good fight.

News of the Week.

The American Neurological Association will hold its next annual meeting in Philadelphia, on June 4, 5 and 6, 1890.

The Iowa State Medical Society will meet at Des Moines, April 16th, 17th, and 18th.

The Medical Society of the Mississippi Valley convenes at St. Joseph, Mo., March 20th and 21st.

The Nebraska State Medical Society meets at Beatrice on May 13th.

The Illinois State Medical Society will meet in Chicago, beginning May 6, 1890.

American Medical Association.—The forty-first annual session will be held in Nashville, Tenn., on Tuesday, Wednesday, Thursday, and Friday, May 20, 21, 22, and 23, commencing on Tuesday at 11 A.M. The addresses will be given on "General Medicine," by Dr. N. S. Davis, Chicago, Ill.; "General Surgery," by Dr. Samuel Logan, New Orleans, La.; "State Medicine," by Dr. Alfred L. Carroll, New York, N. Y.

A Trip to Europe for the Tenth International Medical Congress.—Dr. Robert Newman has published a useful schedule of information regarding the trip to Europe for the purpose of attending the Tenth International Medical Congress. A trip to Europe, from New York to Rotterdam, and return, can be made for $110, first cabin, by the Royal Netherlands and United States Mail Line. The railroad fare, second class, to Berlin is $10.50. The days of sailing are Thursdays or Saturdays, in June and July.

A Hospital in Kearney.—An effort is now being made to establish a small hospital in Kearney, Neb., and the young ladies of the town are actively engaged in raising the necessary funds.

An Apparatus which will Enable Deaf Persons to Hear Public Speakers.—Dr. Francis H. Brown, of Boston, publishes, in the *Boston Medical and Surgical Journal*, the description of an apparatus for the purpose above indicated: "It consists of a trumpet-shaped tin sound-receiver, having an opening superiorly of six inches, and narrowing inferiorly to a diameter of one inch. Its upper end is curved, so that the opening of the trumpet is directed toward the mouth of the speaker. The sound-receiver stands on the desk or pulpit, and is partially concealed by a gas-fixture. At its lower end it fits into the opening of a common tin speaking-tube, which passes down, through and under the floor, to the seat of the lady in the audience; at that point the tube ends in a piece of brass pipe, rising some four inches above the seat, over which the person using it places the bell-shaped end of the flexible conversation-tube now very commonly employed by the deaf." Dr. Brown states that an apparatus like the above was devised by Dr. C. J. Blake several years ago. If we mistake not, some of the churches of this city have had such an apparatus in them for a long time.

The Detective Reporter as a Dispensary Patient.—The scheme of sending a reporter to a dispensary or hospital and letting him or her act the part of a patient and spy is becoming a popular means of making a sensation. Lately a female reporter recounted in a daily paper her experiences at a clinic for diseases of the eye. She was evidently carefully examined and intelligently prescribed for. In return, she publishes criticisms and woodcuts of the physicians and the dispensary, which are as severe as the circumstances would allow. As a matter of fact the only fault really discovered was that some of the physicians came late, and allowed themselves to converse a little instead of attending promptly to the reporter's wants.

The curious spectacle is presented just now, in this city, of a probably insane man, recently discharged from the Ward's Island Asylum, who is busily engaged in trying to secure by legal measures the discharge of a number of lunatics now confined in the asylum.

A New General Hospital has recently been incorporated in this city, called St. Mark's Hospital. The certificate of incorporation says that "the members of said corporation shall adhere to the theory of medical or surgical treatment known as the regular school, and the system of practice of medicine or treatment which shall be applied in said hospital shall be such as is used by regular practitioners and known as the regular-school system."

Dr. Renssalaer Jewett, of this city, died on March 7th, aged seventy-three years. He graduated from the Albany Medical College in 1844.

Sea-sickness.—Dr. J. J. Seiser, of Helena, Mon., writes that in crossing the ocean, several years since, he made some observations which seemed to him to prove that the cause of sea-sickness resides in inefficient breathing. He offered an article on that subject to a London medical journal, but it never saw print. He also asked several steamship companies for permission to experiment with oxygen on board, but was refused. If he is correct in his theory, he asserts, inhalation of oxygen gas should be efficacious in relieving sea-sickness by curing the carbonic acid poisoning, and he says that he would be glad to hear of some one experimenting with it in order to prove or disprove the theory.

Women may be Doctors but not Lawyers.—The Belgian Parliament has decided to admit females to the full practice of medicine and pharmacy, but to exclude them from the legal profession.

The Association of American Physicians holds its fifth annual meeting in Washington, May 20, 21, and 22, 1890. The following preliminary programme is announced: Discussion on "Disturbances of Sleep," by Drs. S. Weir Mitchell and Charles F. Folsom; "Methods of Diagnosis in Diseases of the Stomach," by Francis P. Kinnicutt. Papers: "Inflammations of the Appendix and Cæcum, and the Duty of the Physician regarding them," by Norman Bridge; "Anæsthetic and Non-anæsthetic Hysteria," by Charles L. Dana; "Seizures Characterized by Shock and Loss of Consciousness," by Israel T. Dana; "The Diathetic Causes of Renal Inadequacy," by I. N. Danforth; "Certain Points Relating to Tricuspid Endocarditis, with Specimens," by William W. Gannett; "Antisepsis in Midwifery," by William T. Lusk; "Varicose Aneurism of the Arch of the Aorta," by William Pepper and J. P. C. Griffith; "Natural History of Typhoid Fever," by James E. Reeves; "What Can and Should be Done to Limit the Prevalence of Tuberculosis in Man?" by Edward O. Shakespeare; "Migraine," by Wharton Sinkler; "Etiology of Pleurisy, Especially in its Relation to Tuberculosis," by A. A. Smith; "Report of Cases of Angio-neurotic Œdema," by Samuel B. Ward; "Demonstration of Pathological Specimens," by W. T. Councilman.

Tight Lacing in Monkeys.—In order to test the injurious effects of tight lacing on the respiration, Dr. Lauder Brunton, while in India, made a number of experiments on female monkeys, for the simple reason, as Dr. Brunton ingenuously explains, that they are more like women than dogs are. A monkey was enveloped in a plaster-of-Paris jacket to imitate stays, and a tight bandage was then tied round the abdomen, so as to imitate the band which would sustain the petticoats. They were then given chloroform. The result of the experiments is reported to have been "very marked indeed," so much so that several of the monkeys died very quickly. Dr. Brunton added that the survival of some of the animals experimented upon was probably due to the fact that the diaphragm is able to compensate to a large extent for the enforced loss of chest movement.

The Dixie Doctor is the title of a new monthly medical journal edited by Dr. T. H. Huzza, and published at Atlanta, Ga.

Curing Sterility by Law.—A bill has been introduced in the French Chambers providing, as a remedy for the decline of population, for a tax on all bachelors—an old remedy—and in addition to this, an entirely new remedy, in the shape of a tax on all married people who have no children, and are unable to offer any reasonable excuse for not having any. A recent census of Fifth Avenue, New York, showed an average of about half a child to a family.

The American Climatological Association will meet this year at Denver, Col., September 2d, 3d, and 4th. A number of complimentary excursions will be tendered the visitors, and it is expected that low rates for the trip will be secured.

The Faith-Cure People Give it up.—The faith-cure people have yielded, and will in future call a doctor when their friends are sick, as the law requires. At least so a committee of four, who called upon Coroner Rooney, of Brooklyn, announced. Their spokesman, after saluting the Coroner, delivered the following oration: "We are a committee of the people who worship in Temperance Hall, on Hamilton Avenue. Our people have been considering carefully the action of the authorities toward us. Last night we decided to ask God what we should do. We prayed long and hard. We asked for light. At last we saw the light, and now we have come to say that you are right and we are wrong. Hereafter when we are sick, we will call a doctor, as you and the law direct."

The Alumni Dinner of the Long Island College Hospital, Brooklyn, N. Y.—The twelfth annual dinner of the alumni of the Long Island College Hospital was given at Remsen Hall, Brooklyn, Wednesday evening last. The Vice-President, Dr. Paul H. Kretzschmar, presided, and was toast-master. Speeches were made by Drs. Alexander Hutchins, J. H. Raymond, A. L. Gihon, United States Navy, and George F. Shrady. The graduating class was present and comprised in its number two negroes and a Chinaman.

The State Care of the Insane.—The bill advocating the state care of the insane, as against county care, was discussed before the committee of the Assembly on Wednesday. Professor Chandler, of Columbia College, spoke for the bill, representing the State Charities Aid Association. He said it divided the State in as many asylum districts as there are State insane asylums. Inexpensive detached buildings of moderate size are to be erected on grounds of existing asylums, to accommodate pauper insane now in poorhouses. The total cost of these buildings and furnishings shall not exceed $5.50 per capita. Poorhouse keepers are wholly ignorant of the needs of the insane. For the salaries now paid, persons competent for such work cannot be obtained. The medical attendance in poorhouses is often let out to the lowest bidder, and often to incompetent doctors. Then, too, the care of the insane is often given to raw graduates of medical colleges. The treatment of the insane in a poorhouse is a centu y behind the times. Supervision under one management is much less expensive than the county plan, and patients can be classified, well cared for, and made the subject of proper treatment in State asylums. There were, of course, present the advocates of the county system, who pleaded for cheapness and advanced the absurd proposition that the insane were better cared for in the county institutions than in the State asylums. Bosh! Separate politics and county poorhouse interests from the measure, and the State care of the insane could not reasonably have a dissenting voice. The profession of the State owes it to humanity that the bill should pass, and every medical man composing it should use his best endeavor to that end. Poorhouses for the insane instead of hospitals! For shame!

Whooping-Cough.—A two per cent. watery solution of resorcin sprayed into the nose, throat, and larynx every two hours is a remarkably efficient agent in the treatment of whooping-cough, according to Dr. J. W. Farlow, of Boston.

The Pennsylvania State Veterinary Medical Association held its annual meeting in Philadelphia, on March 4th. Twenty-two new members were received, and the meeting was the largest and most interesting ever held. The following papers were read: "Contracted Feet," by Dr. Rush S. Huidekoper; "Parturient Apoplexy," by Dr. W. H. Ridge; "Is Cribbing a Disease?" by Dr. I. Michener; "Indigestion in Horse, Cow, and Dog," by Professor W. L. Zuill. The election of officers was held with the following result: W. S. Kooker, of Philadelphia, *President;* T. B. Raynor, of Chestnut Hill, J. Curtis, of Bucks County, N. Rechterwald, of Pittsburg, *Vice-Presidents;* S. J. J. Harger, *Recording Secretary;* Robert Gladfelter, *Corresponding Secretary;* Dr. John R. Hart, *Treasurer.*

Skimmed Milk in Philadelphia.—According to the chief inspector of milk of the Board of Health of Philadelphia, there is no law preventing the sale of skimmed milk as whole milk. There is a State law against such substitution, but for some reason the city of Philadelphia was, at the time of its passage, especially exempted from its operations.

Under the Head of "Hydrophobia Cured" an Ohio paper describes the case of a boy, when two and a half years old, bitten by a rabid (?) dog, and suffering from hydrophobia eight years later. The objections to this story are that the period of incubation of hydrophobia averages only seventy-two days and never eight years; and that hydrophobia is invariably fatal.

An International Congress on Alcoholism will be held at Christiania, from September 3d to 5th of the present year. The programme promises to be an interesting one, including as it does the following subjects: (1) The means which have proved so successful in Norway in lessening the evils of alcoholism; (2) the results of the Gothenburg System; (3) the alcohol question in relation to the upbringing of the young; (4) the deterioration of indigenous tribes by the spirit trade; (5) substitutes for alcoholic beverages as weapons in the warfare against alcoholism.

A Parasitic Fœtus.—One of those singular malformations described as "parasitic fœtus" has been attracting some attention at Demerara. A coolie was admitted into the Colonial Hospital suffering from a tumor in the right loin. The man died, and at the post-mortem examination the "tumor" proved to be possessed of a cranium, with hair attached, an imperfect nose and mouth, no hands or feet, but the rudiments of male genitals. The subject of this "autosite" was thirty-two years of age.

Transportation of Corpses.—Only a short time ago a child died of diphtheria in Ravenwood, Ill. The body was removed to Zanesville, O., where, doubtless, sympathizing friends and others "viewed the remains." As a result an epidemic of diphtheria broke out, with five deaths of children at last accounts. In this case there is some question as to who is to bear the blame, it being alleged on one hand that the doctor gave a false certificate, and on the other that the certificate showed the cause of death to be diphtheria; but the railroad company took the responsibility.

Physiology in the Schools.—The New Jersey Legislature has passed a bill requiring the teaching of physiology and hygiene in the public schools, special reference to be made to the effect of alcohol on the human system. Certainly a very complicated study for children.

Prosecuted for Vivisection.—Dr. B. T. Shimwell, of Philadelphia, was called to trial by the Woman's Branch of the Society for the Prevention of Cruelty to Animals, on a charge of needless cruelty to animals. His offence consisted in experimenting upon a dog in order to illustrate a new method of intestinal resection. The hearing took place on March 4th, and the accused was discharged by the magistrate without calling in any of his witnesses, the judge holding that the prosecution had failed to make out any case against Dr. Shimwell.

The Health Board and the Coroner.—There is a quarrel in San Francisco between the Board of Health and the Coroner, because the former granted a permit for burial in a case of death without medical attendance. The Coroner has obtained the arrest of the Health Officer, and a rather stormy time is anticipated.

The Commencement Season has now begun, and, from the reports we have received, there seems to be no falling off in the number of newly made doctors. Ten towns, with seventeen medical schools, report five hundred and eighty-three graduates.

Unsanitary Jails.—The daily papers report that the jails in Marion County, Ind., and in Kansas City, are in a filthy and dangerous condition, and, in the case of the former, complaint has been made to the United States Attorney-General, since United States prisoners are confined there. The Kansas City jail is said to equal any in Russia as regards small cells, absence of ventilation, and filth.

The Corner-stone of the Pennsylvania Hospital was recently uncovered, and the inscription was found well preserved in clear and sharply-cut letters. It read as follows:

IN THE YEAR OF CHRIST
MDCCLV
GEORGE THE SECOND HAPPILY REIGNING
(FOR HE SOUGHT THE HAPPINESS OF HIS PEOPLE)
PHILADELPHIA FLOURISHING
THIS BUILDING
BY THE BOUNTY OF THE GOVERNMENT
AND OF MANY PRIVATE PEOPLE
WAS PIOUSLY FOUNDED
FOR THE RELIEF OF THE SICK AND MISERABLE
MAY THE GOD OF MERCY
BLESS THE UNDERTAKING

A Small Child.—Mason City, W. Va., is proud in the possession of a new-born infant which weighed at its birth one pound.

A New Form of Swindle.—A lady under the care of a Louisville physician not long since received a call from a man who said that he was a collector, and presented a bill of $500 from the doctor. He said that his employer would be glad of a part payment on account, if it was not convenient to settle in full, as he had some notes to meet and was a little hard put for cash. The lady was, however, bright enough not to be taken in, and said she would see the doctor and pay him herself on the following day. The physician was surprised to learn of his bill, as he was still treating the patient, and had not as yet made out his account.

Society Reports.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 27, 1889.

WILLIAM P. NORTHRUP, M.D., PRESIDENT, IN THE CHAIR.

Hemorrhage in and about the Supra-renal Gland.—DR. T. M. PRUDDEN presented a specimen of "Hemorrhage in and about the Right Supra-renal Gland in a Newborn Child."

There was no special incident in the delivery of the male child, which, with much difficulty, was made to breathe at first, and continued to breathe badly and poorly perform its general functions until its death on the fifth day.

The abdominal cavity was filled with dark fluid blood or bloody serum, and a large and old clot lay over the region of the right supra-renal gland. Both kidneys and the remaining abdominal viscera appeared normal, save that closely surrounding the right supra-renal gland was a dense, firm, ovoidal blood-clot, about 4 ctm. long, 3 ctm. wide, and 2.5 ctm. thick. The supra-renal gland was itself apparently unchanged, save by pressure, and a considerable infiltration in several places with blood.

Hemorrhage in and about the supra-renal gland is of rare occurrence in adults, but is not very infrequent in the new-born; it is most apt to be one-sided.

As to the cause of these hemorrhages, while they have in the various hitherto described cases been associated with the hemorrhagic diathesis, with leukæmia, with disturbances of the venus circulation, with fatty degeneration and inflammation of the walls of the blood-vessels, and with Addison's disease, our actual knowledge of the causes is actually very meagre.

THE PRESIDENT remembered seeing a case in a child where one supra-renal capsule showed hemorrhages with quite extensive destruction of the gland-tissue. In this case hematoidin crystals were found. A dirty color of the skin attracted attention before death.

Coccidium Oviforme.—DR. FREEMAN presented some specimens and a paper on "Coccidium Oviforme (Psorospermiæ)."

This protozoon, which is parasitic of animals, is of interest because it is very common in rabbits, forming nodules, most often in the liver, sometimes in other organs which may be mistaken for tubercles; also because it can produce the same lesion in man and may cause death. The liver is by far the most frequent organ invaded.

In the liver of the rabbit these nodules occur mostly in the neighborhood of the gall-bladder; they vary in diameter from microscopic to two or three centimetres. A section through a nodule shows under the microscope a cavity surrounded by connective tissue and lined by spores or psorospermial and by more or less distorted columnar epithelium. From the walls many irregular projections extend into the cavity; these consist of a connective-tissue framework supporting a large number of spores. Detritus and coccidia lie free in the cavity. The coccidium is an oval shaped body surrounded by a thick membrane and containing a coarsely granular substance, sometimes distributed throughout its interior, sometimes confined to a spherical ball. For the most part the walls of the cavities are lined with spores piled on each other; between these and the connective tissue one can see sometimes nucleated epithelial cells; more rarely is the wall lined with apparently normal columnar epithelium. The coccidia are also found in the bile-passages and gall-bladder.

The question of the real significance of these nodules caused much speculation until Remak,[1] in 1845, first noted the resemblance of their contents to psorospermiæ.

Leukert[2] holds that the cavities are developed from bile-passages which have been invaded by the spores, and gradually dilated. The projections into the cavity he explains as the remains of tissue formerly existing between neighboring bile-ducts which have united. The spores, he says, grow within the epithelial cells lining the gall-ducts, and five or six may occupy one cell. Such growth within the cells I have been able to demonstrate when there are but few spores. When there are many spores lining the cavity I find often no trace of epithelium; sometimes, however, there is a nucleated cell between the spores and the connective tissue. The spores, having reached maturity in the walls of these cavities, become free within the cavities, where they are enveloped in a thick membrane, and take an oval form. A micropyler opening is described at the more pointed end. The contents of the coccidium are granular and at first distributed throughout, but later collected in a spherical body. The coccidia then get into the bile-passages, then into the intestines, and finally are discharged.

After being discharged the contents of the coccidium segregate, forming four bodies which finally become sickle-shaped. The protozoon is now ready to enter a new host. Cultures of this organism have been made in chromic-acid solution, but its period of incubation is not yet fixed; results vary from two weeks to months. Animals become infected by taking into their stomachs these coccidia containing the four sickle-shaped bodies. It is thought that the coccidia disintegrate in the stomach, discharging the sickle-shaped bodies, which draw themselves into a ball, and taking on amœboid movements reach the liver through the bile-passages.

The great frequency of the disease in rabbits is noteworthy; in ten consecutive autopsies on rabbits, I found coccidium oviforme nodules in every case. Psorospermiæ have also been found in sheep,[1] pigs,[2] and monkeys.[3] They have been described in the lung of a monkey[5] in nodules looking grossly like tubercle and varying in size from microscopic to miliary.

The first case occurring in man, and recognized as psorospermiæ, was that of Grubler, of Paris, reported in 1858. There were twenty tumors in the liver, varying in size from that of a chestnut to an egg. Grubler examined the contents and thought the coccidia were the eggs of distoma, but he failed to find any worms in the intestines.

Leukert recognized its true nature. He mentions its occurrence in man in a case of Dressler, and two cases of Perls, of Giessen, also two cases of Lindemann, one of the kidney and the other of the hair, but as to the correct diagnosis of these latter cases there seems to be some doubt.

Kunstler and Pitres [4] found coccidia in a pleuritic exudation in man.

The molluscum bodies seen in molluscum contagiosum were thought by Ballinger [5] to be psorospermiæ, but this view is not generally accepted.

Darer, in an article entitled "De la Psorospermose Folliculaire Vegitante" [6] reports two cases of a characteristic skin disease. In the horny mass under the hair-follicles the author found round cells with double encircling membrane and granular contents and a medium sized nucleus. These he takes to be coccidia; he failed in efforts to cultivate and inoculate; one patient was sick nine years without infecting her husband.

Darer believes that a case reported by Dr. James C. White as keratitis follicularis [7] is similar to those described by him.

In conclusion I may mention the pseudo-tuberculosis of rodents. This disease causes nodules in the spleen, liver, kidney, and lung, also enlargement of the lymphatic

glands and inflammation of lymph-follicles in the intestine. The lesion has the gross appearance of tubercle, but grows much faster. It was first recognized by Malassez and Vignal,[1] has since been studied by Eberth,[2] and more recently by Pfeiffer,[3] who attributes to it a specific bacillus of which he made cultures and inoculations.

Note.—At a meeting of the Pathological Society of London, December 17, 1889,[4] a specimen of coccidium oviforme of the ureter and kidney occurring in man was presented by Mr. Bland Sutton.

Dr. Prudden thought that the paper gave the idea that the disease was more common than it really was. It generally occurred in groups, as in the case recorded, and was found in the animal-houses, especially toward the end of the season, suggesting the spread of the disease from one to another.

Dr. Freeman said that the animals which he had examined had been but a short time thus exposed, but had come from the same place before this.

Dr. H. P. Loomis said that he had lately examined a number (forty) of rabbits, and as even their livers showed no such lesion he was inclined to think the disease less frequent than the paper would indicate.

Extension of Tuberculosis in the Lung by Aspiration.—Dr. John S. Ely presented some specimens illustrating the "Extension of Tuberculosis in the Lung by Aspiration."

In 1883 Weigert summed up the prevailing theories regarding the spread of tuberculosis in the body substantially as follows:

I. By direct extension of a tubercular mass in the tissue in which it exists.

II. By mechanical transport of tubercle bacilli in various channels of the body (exclusive of lymph- and blood-vessels), as, for example, through the air-passages during coughing, or in the alimentary tract in swallowed bits of sputum.

III. By penetration of bacilli into lymphatics and transportation in the lymph-current.

IV. By penetration of bacilli into blood-vessels and dissemination in the blood-current.

The exhaustive study accorded to tuberculosis during the past six years has added nothing to this list.

The specimen which I present this evening exemplifies the second mode of extension of the tubercular process, that by mechanical transport of the bacilli, in this instance through the air-passages. The specimens are sections from the lung of a patient who had for a long time suffered from bronchitis, as the result of which bronchiectases had formed in the lung. Some of these are visible along one side of the sections. The accompanying cut roughly portrays the topography of a portion of one of the sections.

There is but slight inflammation around the bronchiectases and in the lung-substance. What is especially noteworthy is the entire absence of any tubercular inflammation in the sections, except in the immediate neighborhood of the dilated bronchi. This is in itself significant, but that which renders the proof almost positive that it is through the bronchial tubes that the extension of the tubercular process has occurred, is a small mass of tubercle tissue on the wall of one of the bronchiectatic cavities. This consists of a collection of small spheroidal cells, in the centre of which cheesy degeneration is apparent. This nodule of tubercular inflammation seems to have developed from the inner surface of the dilated bronchus, and appears to have no connection with any tubercular tissue in the immediate neighborhood from which it might be considered to be an extension. I am compelled to believe it to have resulted from the lodgement of tubercle bacilli upon the wall of the bronchus and their subsequent development there.

It seems to me that this mode of dissemination of the tubercular virus must be very frequent in cases in which an advanced tubercular nodule exists in the lung, for in the forced inspiration immediately preceding a hard cough, many particles of cheesy matter or sputum might readily be aspirated into the bronchial tubes in the neighborhood of the disintegrated lung-tissue.

It has now been my privilege to present to the Society at different times specimens illustrating all the modes of extension of tuberculosis in the body enunciated by Weigert, except the first, that by direct growth of a tubercular mass, which, being self-evident, needs no demonstration.

A Heart from a Case of Angina Pectoris.—Dr. H. P. Loomis presented "A Heart from a Case of Angina Pectoris," with the liver showing peculiar whitish-gray patches.

F. G——, aged forty-six, began to suffer with what he called "heart trouble" five years before his death. During four years of this time he was confined to his house two or three weeks at a time at different periods. A year before his death he came under my observation, when he was "water logged;" there was cardiac asystolism, acute pulmonary œdema, and he was suffering almost constantly with severe anginal pains. At my first visit it did not seem possible that he could live more than twenty-four hours.

Nitrite of amyl instantly stopped the anginal pectoris, and Fothergill's pills relieved him, so that by the end of two weeks his œdema had disappeared and he was fairly comfortable. During the past year he was unable to leave his rooms, and most of that time was compelled to assume a sitting posture. He suffered daily from attacks of angina pectoris, which could only be relieved by nitrite of amyl "pearls;" morphine in full doses gave no relief, and nitroglycerine, continued for a long time, did not diminish the number or severity of the attacks.

The patient took during the year over one thousand two hundred of these "pearls," each containing five drops of nitrite of amyl, the last giving him just as complete relief as the first. His heart's action was irregular and intermittent, and physical examination gave the signs of general cardiac hypertrophy and dilatation, with extensive aortic obstruction and insufficiency. His cardiac impulse at times was forcible, but usually feeble and diffuse. His urine contained a moderate amount of albumin, but no

[4] Lancet, December 21, 1889.

casts were ever found; during most of the time his urine contained an excess of uric acid. At times he suffered from excessive anorexia, which could only be relieved by washing out the stomach. Dyspnœa and œdema of the feet was never present after the first exhibition of Fothergill's pills. The prominent symptoms of the case, independent of those ordinarily present in valvular lesion with cardiac dilatation, were: First, the constant recurring attacks of angina pectoris; second, the length of time the patient lived after he had developed the symptoms of extensive cardiac insufficiency; and also the fact that his urine at no time showed any evidence of tubercular changes in the kidney. The explanation of the peculiar appearance presented by the liver is a point of special interest.

Autopsy, made twenty hours after death.—The heart was the largest I remember ever to have seen—a typical specimen of *cors bovis*. Its weight, after removal from the body, when emptied of blood, was one and three-fourths of a pound. The left ventricle was greatly dilated, with slightly hypertrophied, dense, muscular-looking walls one and one-fourth inch in thickness. The aortic valves were indurated, retracted, and eroded. The aorta, for two inches above its origin, was dilated, exceedingly atheromatous, and covered, in places, with calcareous plates. The right ventricle was extensively hypertrophied and dilated, as were both auricles. Microscopical examination showed moderate interstitial myocarditis, with perfectly normal muscle fibres. The lungs were normal, with the exception of hypostatic congestion in the lower lobes. The liver weighed five and one-half pounds. Scattered throughout its entire substance were whitish-gray patches, varying in size from a pin's head to a small pea. These gave the liver a very unusual appearance, and suggested areas of connective tissue increase, but microscopical examination showed that the only lesion of the liver was excessive passive congestion, and that the white areas were capillary hemorrhages which had torn apart the lower cells. The outline of the red blood corpuscles were very distinct. They had not degenerated. The kidneys were very much enlarged and of normal appearance. The microscope showed extensive congestion of the capillaries, with a slight breaking down of the free borders of the tubular epithelium in place. There was no connective-tissue increase.

Dr. Roosevelt called attention to the fact that we find angina with perfectly normal hearts, with the so-called typical lesions and with atypical lesions. He thought that no very definite relation had as yet been demonstrated, and was inclined to think that there must be some constant lesion not as yet known.

Dr. Loomis also presented a specimen of "Scirrhous Carcinoma of the Pylorus" which had caused death, but in which the symptoms had been so atypical that a positive diagnosis had not been made.

The Result of Hip-joint Exsection.—Dr. T. H. Myers presented a specimen showing the result of hip-joint exsection, in a child four and a half years of age, nine months after the operation.

The case was one of hip-joint disease, with abscesses, pain, and lack of suitable means for conservative treatment.

In the track of an abscess, by the usual Langenbeck incision, the head of the femur was removed. Abscess cavities were found within it. The limb was fixed as much as possible by the long lateral splint, and extension also applied. In two and one-half months the child was allowed up, and the next month began to bear some weight upon the limb. The joint seemed firm, and no aid was sought by applying the hand to the hip or thigh. The motion in the joint at seven months was very fair in deed. Flexion was especially good, while abduction and adduction were allowed to a slight degree; and though there was this free motion, there was very little telescoping of the joint. The shortening amounted to half an inch only. Dissection shows the lack of telescoping to be due in greatest part to the very well defined upper and posterior border of the acetabulum, which has not apparently suffered from the disease. The ligaments and muscles about the joint, also, have accommodated themselves to the altered anatomical relations, and enclose the joint firmly and closely. It is unfortunate that this cannot now be shown in the specimen presented.

The origin of the ligamentum teres shows a small cartilaginous nodule, probably formed since the operation.

Dr. Lynde, to whom I am indebted for the history of the case, assures me that the neck of the femur is shorter than it was at the time of the operation. It now barely extends beyond the intertrochanteric lines. The opposing surfaces are now covered with a strong, smooth, fibrinous membrane, and articulate almost smoothly, giving rise to an albuminous crepitation only.

There are still two small circular areas on the femoral neck, covered only by softer granulations; at no point, however, is there any exposed bone, nor is there evidence of any active disease in the joint.

Ollier has lately published [1] the ultimate results in his series of fifty cases of excision of this joint, and it is instructive to note that those cases which recovered with more or less free movement in the joint, though enabled to sit gracefully and conceal their defect more readily, could not stand the long walks and other violent exercise which the ankylosed joints bore with impunity.

The child from whom this specimen was removed died nine months after operation of general tuberculosis. I hope Dr. Northrup, who made the autopsy, will give his opinion as to the relation between the two. Was the hip-joint disease primary or secondary?

The President said he thought the case a very good one of secondary hip-joint disease, and the best example of cured pulmonary tuberculosis that he had ever seen. The tubercles were present in great numbers in the meningeal lesion, but their origin he had been unable to discover.

The Society then went into executive session.

Stated Meeting, December 13, 1889.

William P. Northrup, M.D., President, in the Chair.

Dr. G. C. Freeborn presented the following card specimens:

Chronic Ovaritis.—A series of six ovaries illustrating chronic ovaritis with the formation of follicular cysts. These ovaries have been removed by laparotomy. A transverse section through a Fallopian tube, showing chronic suppurative salpingitis. Tube measures one and one-fourth inch in diameter. A section through a small multilocular cyst growing from the cyst-wall of a large multilocular cyst of the ovary.

A Preserving Fluid.—This specimen had been fixed in Flemming's chromic and acetic acid mixture (one per cent. aqueous solution of chromic acid, 20 parts; two per cent. aqueous solution of hydric acetate, 4 parts; water, 70 parts). The specimen was suspended in one hundred times its volume of the above fluid for forty-eight hours; then washed in water until all color ceased to come away; then hardened in seventy per cent. alcohol. After removing the specimen from the fixing fluid, the walls had the consistency of soft leather, and when the specimen was cut around, the walls of the various cysts did not collapse, but retained their normal position.

From the results obtained with this specimen, and from experiments that are now being made with large cysts, I think this fluid will prove valuable as a preservative for gross specimens of cystic degeneration.

The President asked what was the white material seen in one of the specimens presented.

Dr. Freeborn replied that it was apparently the contents of the cyst. One of the specimens showed a slight hemorrhage, which the speaker regarded as an accidental

[1] Bull. Acad. de Med., Paris, 1889, 3 S. xxi., 693.

hemorrhage occurring during the removal of the cyst. The cases were all operative ones, and the histories were not known.

Dr. Boldt said that there was always a history of ovaritis in cases of this kind.

Dr. Biggs said that he had very frequently found cystic changes in the ovaries without the slightest evidences of inflammatory processes.

Dr. Boldt replied that he had spoken from a clinical standpoint only. All operative cases gave this history.

Dr. T. M. Prudden wished to call particular attention to the mode of preservation that had been used in these cases, for it was usually a very difficult thing to preserve cystic adenomata of the ovaries well.

Photogenic Bacteria.—Dr. Prudden then showed some cultures of one of the forms of "photogenic bacteria." A culture on agar-agar, when shown in the darkened room, emitted a phosphorescent light, and a flask of water containing some of the bacteria became luminous when agitated. Several forms of these photogenic bacteria have been isolated and described, some being obtained from phosphorescent fish, and others from crabs. The latter had been shown to be pathogenic.

Melanotic Sarcoma.—Dr. H. J. Boldt presented a specimen of "melanotic sarcoma" removed from the belly of the gastrocnemius muscle of a young man. The tumor had grown very slowly at first, but during the last few months had caused some trouble. The centre of the growth was fluid, and was found to contain blood. The walls of the cyst were melanotic. A large portion of the belly of the gastrocnemius muscle was removed with the tumor, as were also the neighboring glands, which were found to be likewise melanotic.

Sarcoma of the Uterus.—A second specimen was one of "sarcoma of the uterus," complicated with ovarian tumor. The woman had had hemorrhages for some time. The ovarian growth was first removed and then the uterus. The patient died, and at the autopsy there was found to be chronic interstitial nephritis, and the heart was very small, being no larger than that of a child nine years of age.

Shot Wound of the Chest—Dr. H. M. Biggs presented a specimen of "shot wound of the chest" in a child eleven months of age. The child had been shot fifteen days before her death, the bullet entering near the right nipple. It struck a rib and was deflected, passing through the diaphragm and into the kidney. At the autopsy the right lung was found to be completely collapsed, and there was pneumo-thorax, with a fibrinous exudation on the pleura, but without any effusion in the pleural cavity. There was, in addition, a very recent general "miliary tuberculosis." The parietal pleura on the right side contained thousands of miliary tubercles, and there were also tubercles in the brain and other organs. There were no evidences of any old tuberculous process. Although miliary tuberculosis was rare in so young a patient, the speaker had seen it in a child of eleven weeks.

The Society then went into executive session.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 20, 1890.

Alfred L. Loomis, M.D., President, in the Chair.

The Therapeutics of Heart Disease.—Dr. H. N. Heineman, in a paper on this subject, gave a preliminary outline of the anatomy of the heart, an understanding of which, as well as of the function and pathology, was necessary in the treatment of its lesions. The lesions of the heart might be divided into two great groups. The first included congenital conditions of the heart and arteries. An abnormally small heart, associated with imperfectly developed blood-vessels, was not rare. The second group included cases of acquired disease. These were due primarily or secondarily to sclerotic, fatty, or other degenerative changes acting immediately upon the heart or the vessels, or mediately through disease of other organs, as of the kidney. Then there were conditions, the cause of which were more or less obscure, such as tachycardia, abnormally slow heart, interrupted heart-beat, and angina pectoris. The condition of the blood, plethora, and hydræmia frequently furnished important indications for treatment.

A brief *résumé* of the various cardiac conditions which we were called upon to treat was given: Hypertrophy, concentric or excentric, alone or in combination with dilatation; then dilatation, alone or with hypertrophy; mitral disease, stenosis or insufficiency; aortic disease, stenosis or insufficiency; mitral and aortic disease, disease of the pulmonary artery. As causes there might be waxy, fatty, or fibrous degeneration or sclerosis; inflammations; infectious disease; obstructed circulation, which acted secondarily through changed blood state; tumors; emphysema and other pulmonary disease; renal affections.

The Indication for Treatment.—In all cases it was insufficiency of the cardiac muscle which furnished the key note for treatment. It was the natural tendency of a viscus to seek to restore itself to the normal state or adapt itself to new conditions. The diseased heart, by a system of compensatory hypertrophy, sought to resume its normal function.

Hygienic, Dietetic, Remedial, and Chemical Agents.—Such was the division which the author made of agents employed to combat cardiac disease. Some acted temporarily, some permanently, some locally, others constitutionally, while a few acted directly upon the heart muscle, most of them, however, indirectly, by changing the blood state or restoring nerve-tone; finally, some acted whose rationale was not entirely clear.

Remedial Agents.—Under remedial agents he mentioned as some of the most important digitalis, strophanthus, convallaria, sparteine, ergotine, and general tonics, including strychnine, hyoscine, iodide of potassium, and galvanism.

Remedies for a more temporary effect were, alcohol, caffeine, tea, chloroform, ether, camphor, musk, nitroglycerin, nitrite of amyl, opium, counter-irritation, phosphorus, venesection.

Dietetics included the regulation of liquid and solid foods, and absolute control as to the character and quantity of each, depending upon indications found in the condition of the cardiac muscle and blood state. The mechanical included walking, hill or mountain climbing, gymnastics, and other forms of exercise.

Speaking of the treatment historically, the author said Stokes introduced a new departure, which, by many, was too little heeded when he recommended greater and increasing amount of exercise according to the individual case, and suggested meat diet, abstinence from fatty food and vegetables. Some wine and whiskey was allowed, except in advanced stages.

Strophanthus and convallaria gave better results combined than separately. He preferred the tincture of strophanthus to the alkaloid. The previous habitual use of tea or coffee would furnish an indication as to their value in heart affections. Musk, so long recommended, has come to be looked upon with scepticism, but unjustly so. Too small doses would account for its inefficacy. Strychnine, quinine, and nux vomica had a beneficial effect upon the unstriped muscular fibres of the heart. It was not necessary to dwell upon the virtues of digitalis. Its cumulative action might be prevented by use in connection with sparteine.

The Mechanical Treatment.—In cases of degeneration of the heart-muscle some of the healthy fibres remaining might hypertrophy and even predominate over the degenerated fibres, and action be restored to a partially useless muscle. By proliferation new fibres might form, and fatty degeneration and infiltration lose their influence and return to a normal, or nearly normal, function be

brought about. Observation had shown that the heart-muscle itself, although not of the striped variety, was not beyond these influences. Exercise increased the functional activity of the heart, causing an increased flow of blood to its nutritive vessels and improved nutrition. He had made an autopsy on a 'longshoreman, aged sixty-nine, who had for fifty-two years carried a mitral lesion, which showed that a pursuit requiring more or less daily strain was not necessarily contra-indicated by the presence of a heart lesion.

The Sphygmograph was of value as showing the beneficial influence of properly regulated exercise, manifest in the improved tracings. *A priori*, stenosis of the mitral orifice was a contra-indication to the mechanical treatment of cardiac disease rather than regurgitation. Mechanical treatment in such a case would only increase the hindrance to the venous circulation, for the more quickly the fluid was sent past the obstruction the more the obstruction became felt. In stenosis of the aorta, however, if not followed by compensating hypertrophy of the left ventricle, the mechanical method found application.

In Insufficiency of the Valves, more particularly of the left side, nature made a strong effort at compensation. This effort, however, might be aided by the mechanical method. How long it should be employed in these cases was a very serious question. They should be closely watched, for while compensation might be attained, it was always a question how long it would be retained.

Contra-indications to the Mechanical Method.—As soon as marked circulatory disturbance and increased dilatation of the right ventricle became apparent, the mechanical method was contra-indicated. Where stenosis and insufficiency were combined, the answer to the question, whether the mechanical treatment should be employed, would depend upon whether the stenosis or the insufficiency predominated.

In Fatty Degeneration or infiltration, associated with plethora or hydræmia, the mechanical method, carefully applied, associated with dietetic means, was a powerful restorative agent of lost compensation.

Dietary Treatment.—When there was plethora and commencing heart disease, albuminoids with a diminished amount of fat-producing food had been recommended. By abstaining from fluids fat-absorption was promoted. In cases with normal or diminished fatty deposit, with diminution in cardiac force and anæmia and hydræmia, there was also an indication for albuminoids and regulated diet.

Exercise in the Open Air.—Dr. Francis Delafield thought it was difficult to discuss the question of the treatment of chronic heart disease, for this term included a great variety of conditions, each one demanding its particular form of treatment. Probably what was expected of the speakers this evening was to say something on certain points brought out in the paper. Regarding the so called mechanical treatment of heart disease there was perhaps no sort of treatment worthy of greater attention than this. It was first presented to us in a more or less crude way, and with our preconceived notions of heart disease we were shocked by it. Time has shown, however, that, excluding a certain number of cases which required rest in bed, or confinement to the house, there remained a considerable number of cases of all kinds which unquestionably were benefited by exercise in the open air. That seemed to be really the practical outcome of the mechanical treatment. It was not necessarily mountain climbing, it was not necessarily gymnastics, but exercise in the open air adapted to the condition of the heart and of the patient. It should be adapted to the heart action, not the heart lesion. It was of benefit in improving the general health of the patient, in enabling him to take more nourishment, in improving the circulation, in diminishing the disposition to venous congestion; the heart participated in the general improvement, and if the conditions of the valves was to be benefited it could be done in this way. But while a great many of the patients were improved, none probably were cured, and in most of them the improvement lasted only a moderate length of time.

A Question of Oxygen.—Dr. William H. Thomson said he had been long led, in considering the treatment of heart disease, to ask himself, what is it that muscles need most, and to find the answer in the word oxygen. He thought it could be demonstrated that throughout the whole animal kingdom muscular power was dependent upon the amount of respiration. For that reason the insect tribe had muscular power phenomenally greater than living creatures which breathed with the lungs. For that reason, also, the women among nomadic tribes were as strong as the men. We now know that the muscles of the body have another function to perform besides that of contraction, namely, to act as furnaces to the body. There was more carbonic acid generated by a muscle than by any other tissue, which fact meant that the muscles used up more oxygen than any other tissue. Their function was double—to contract, and to produce animal heat.

Take Iron and Camp Out.—The only service of iron in the body was to aid in breathing, and he placed it among the foremost remedies in cardiac disease. Next to it was the remaining out-of-doors as much as possible. Patients with heart disease should have their sleeping-rooms better aired than others. Here was the explanation of the entire benefit derived from mechanical treatment. No other treatment could be compared in value to camping out.

Cardiac Changes usually Secondary to Arterial.—In our hospitals the cases of heart disease in post-adult life gave evidences of being secondary usually to arterial changes which caused resistance to the flow of blood. Here there were two indications, the one to increase the cardiac systole by neurotics, which could have only a temporary effect, the other to relieve arterial tension and reduce to a minimum nervous contraction of the arteries; the latter indication was best met by out-of-door life.

Opposed to Increasing the Albuminoids.—He strongly disagreed, he said, with the recommendation to increase the albuminoids; or, rather, he would change their form, limiting them almost exclusively to fermented milk. Thus he would throw as little work as possible on the kidneys. Neurotics should be used only as adjuvants.

Digitalis the Best but Most Abused Cardiac Stimulant.—Dr. S. S. Burt approved of exercise, but it should be in the open air, and to the extent only of filling the tissues to their utmost with oxygen. Regarding medicines, he had found that digitalis, while one of the most useful in cardiac disease, yet was the most abused. It was not called for where there was compensation. But the general practitioner, as a rule, seemed to give it in all cases of cardiac disease, and thus the medicine was made to do perhaps more harm than good.

Criticisms on the Mechanical Treatment.—Dr. Richard Van Santvoord thought the author had hardly given sufficient weight to the criticisms which had been made on the mechanical treatment, particularly in Germany, where it also had its most enthusiastic advocates. Cases had been reported in which it had been shown to have done actual harm. He also said it was important where there were symptoms which might be attributed to heart disease, when a cardiac murmur was present, to assure one's self that some other condition was not the real cause of the patient's suffering. He related such a case in which the apparent cardiac symptoms were due to neurosis connected with delayed menopause.

Three Indications.—The President thought there were three indications in the therapeutics of heart disease: First, good arterial blood; second, rapid removal from the system of all retrograde metamorphoses; third, the maintenance of the normal condition of the trophic nerve-apparatus of the heart. It was pleasant to find the discussion to-night directed largely to the nutrition of the

heart. We had left discussion of valvular diseases, and brought it under the one head of the condition of the heart muscle.

The Question of Rest and Exercise could not be Flippantly Answered.—He had found it one of the most difficult points to determine whether a given patient with cardiac disease should have rest or exercise, there could be no difference of opinion regarding the importance of hygienic surroundings, of oxygen, sunlight, regulated diet, and freedom from excitement. But to be able to say whether the cardiac hypertrophy had or had not passed the point of compensation, whether the increased muscular power which compensated for the valvular lesion had or had not passed its limit, seemed beyond our present knowledge. He did not think it safe to tell a patient with heart disease whom one had seen only once or twice to go into the country and exercise, for he had known two or three to be killed in that way. It was necessary to keep close watch of the patient, especially where there was beginning loss of compensation. In patients beyond middle life very little exercise was all that could be safely prescribed. It was better for them to be at the seaside than in the mountains.

Regarding the trophic nerve-apparatus of the heart, he hoped we would soon know more about it. Medicines were only temporary expedients. When cardiac tonics in the form of drugs were necessary the time had passed when exercise was safe.

Dr. Heineman made some closing remarks.

The Functions of the Cerebellum as Indicated by Recent Experiments.—Dr. E. D. Fisher read part of a paper with this title. The portion read contained a detailed description of experiments on seven or eight dogs, one monkey, and one pigeon, made in the Loomis Laboratory, consisting in removal of more or less of the cerebellum and observing the after-effects on the animal with relation particularly to co-ordination. One fact stood out very clearly, he said: that it required removal of a very considerable amount of the cerebellum to produce any but very fleeting symptoms. They had confirmed once more the statement of previous experimenters with regard to lesions of the lateral and central lobes. They had shown that mechanical irritation of the cerebellum caused no ocular symptoms or sensory disturbance. In regard to psychical function, certainly no change was observed in temperament or intelligence. The influence on the sexual instinct was noted in one case, that of a dog in which a part of one lateral lobe of the cerebellum was removed. The dog afterward manifested usual sexual power. There was more or less loss of co-ordination, seemingly without loss of power, corresponding usually to the side operated upon and the extent of the injury. It was transient when the lateral lobes were the seat of the experiment. A number of the dogs subsequently succumbed to abscess or hemorrhage.

Dr. W. Gilman Thompson, who had witnessed these experiments, thought they proved pretty definitely that there was a kind of inco-ordination which was caused by lesions of the cerebellum which differed from those forms due to lesions of the cerebrum and cord. In speaking of inco-ordination it was important, if possible, to distinguish between these three varieties, and perhaps others. It was observable in these animals that the complete loss of co-ordination was fully regained in a certain number of days. It seemed that other portions of the brain or cord adapted themselves to do the work of the portion which had been destroyed.

A Foreign Body in the Eye for Six Years.—Dr. Guiot reports in *L'Année Médicale de Caen* for November, 1889, the case of a man who had received an injury to the eye six years previously. There was considerable reaction at first, but this soon subsided and all signs of a local inflammation passed away. Examination showed the presence of some foreign body beneath the conjunctiva which, on removal, was found to be a splinter of bark from a tree.

New Instruments.

AN IMPROVED ANTISEPTIC LOCK FOR SURGICAL INSTRUMENTS.

By GEORGE M. EDEBOHLS, M.D.,

NEW YORK.

The cut represents the lock applied to the well-known McBurney needle-holder. It may be applied to any surgical instrument requiring any other than the obstetric lock.

One blade has, at A, a low, spherical elevation fitting into a shallow depression, B, of corresponding shape, on the other blade. This constitutes a ball-and-socket joint easy to cleanse. The double shoulder serves to impart steadiness and firmness to the entire instrument, preventing lateral displacement of the jaws, as well as of the handles, when in use.

The French lock, so long in use, with the shoulders attached to pivot, as well as the more recent form with a pivot on one blade, a corresponding hole in the other, and a shoulder anterior or posterior to lock, present minute recesses, corners, and holes difficult to keep properly clean. This objection is overcome by what I have ventured to designate an improved antiseptic lock.

The lock was presented to the Section of Obstetrics and Gynecology of the New York Academy of Medicine, at the January, 1890, meeting. It has been applied by the Messrs. Reynders & Co. to various instruments

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 2 to March 8, 1890.

Hoff, J. Van R., Captain and Assistant Surgeon, Leave of absence for one month granted. Par. 1, S. O. 26, Department of the Missouri, March 5, 1890.

Kimball, J. P., Major and Surgeon. Leave of absence for twenty days granted. Par. 1, S. O. 25, Department of the Missouri.

Official List of Changes in the Medical Corps of the United States Navy for the week ending March 8, 1890.

Schofield, W. K., Medical Inspector. Ordered for examination preliminary to promotion to Medical Director.

McMurtrie, D., Surgeon. Ordered for examination preliminary to promotion to Medical Inspector.

Gates, Manley F., Assistant Surgeon. Detached from Navy Yard, League Island, and ordered to the Kearsarge.

Harris, H. N. T., Assistant Surgeon. Detached from the Kearsarge and ordered home.

A Scarcity of Doctors.—There is said to be a great dearth of medical practitioners in Hayti, many even of the larger towns in that uneasy island being without a doctor of any sort. Life in Hayti is not pleasant enough to tempt many to take up their residence there.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 8, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	11	3
Scarlet fever	72	9
Cerebro-spinal meningitis	4	6
Measles	144	11
Diphtheria	125	35
Small-pox	0	0
Varicella	5	0
Cholera	0	0

The Merritt H. Cash Prize.—The Medical Society of the State of New York offers a prize of $100, payable from the Merritt H. Cash prize fund, for the best original essay on any medical or surgical subject. The conditions are: That the competitors shall reside in the State of New York; that the essays shall be either printed or typewritten; that each essay shall be designated by a motto on the title-page; that a corresponding motto, together with the name of the writer, shall be enclosed in a sealed envelope and attached to the essay; and that all essays shall be sent to the Chairman of the Committee on Prize Essays, Dr. George F. Shrady, New York, prior to January 1, 1891. Other members of the committee are Dr. Daniel Lewis, of New York; Dr. Eugene Beach, of Monmouth.

F. C. Curtis, *Secretary.*

Medical Society of the State of New York,
Albany, N. Y., March 1, 1890.

Tenth International Medical Congress.—In connection with the Tenth International Medical Congress, to be held in Berlin, between August 4th and 10th, there is to be an International Medical and Scientific Exhibition. The exhibits will be of an exclusively scientific nature, as follows: New or improved scientific instruments and apparatuses for biological and strictly medical purposes, inclusive of apparatuses for photography and spectral analysis as far as applicable to medicine. New objects and preparations in pharmacological chemistry and pharmacy. New foods. New or improved instruments, subservient to any of the departments of medicine, including electrotherapy. New plans and models for hospitals, convalescent homes, and disinfecting and bathing institutions and apparatuses. New arrangements for nursing, including transportation, baths, etc. New apparatuses in hygiene. Applications or inquiries inscribed "Ausstellungs-Angelegenheit," and accompanied with a printed card containing the name and address of the firm thus applying, ought to be directed to the Secretary-General, Dr. O. Lassar, Carlstrasse, No 19, Berlin, N. W., Germany. R. Virchow, *President;* E. von Bergmann, E. Leyden, W. Waldeyer, *Vice-Presidents;* O. Lassar, *Secretary-General.*

The Thomas Hip-splint.—Dr. Wallace Blanchard, of Chicago, writes in *The Medical Standard* for January, 1890, claiming that the so called Thomas hip-splint was used by himself in the treatment of hip disease five years before Mr. Hugh Owen Thomas, of Liverpool, brought the apparatus to the attention of the profession. He adduces in support of this claim a letter from Dr. Edmund Andrews, of Chicago, in which the writer states that Dr. Blanchard used the splint in his wards at Mercy Hospital in 1872, three years before Mr. Thomas published his book. If this be so, and we do not for a moment doubt it, Dr. Blanchard should have published a description of his splint at the time that he first employed it and found its working satisfactory. If he failed to do so, and Mr. Thomas devised a similar splint (not knowing of Dr. Blanchard's invention), and published an account of it to the profession, he is justly entitled to the credit of the invention, and there is no injustice in attaching his name, instead of Dr. Blanchard's, to the splint. The world has no means of knowing of an invention, except through its publication.

Raising the Standard of the Medical Profession.—Dr. Mareell Hartwig, of Buffalo, N. Y., sends a plan for raising the standard of the profession in this country, which is, he thinks, more practical, as well as more consistent with the liberty of the citizen, than any others which have yet been proposed. The State should establish a new class of medical practitioners, called "State physicians," or any other name that might be chosen, whose right to the title should rest upon the fact that they had passed an examination before a board appointed by the governor. From this class should be appointed all public medical officers, and only these should be allowed to appear in the courts as expert witnesses. Other practitioners might exist as now, and the people should have the right to select them, if they choose, in preference to the State physicians. But it would not be long before the State physicians would be recognized as possessing better qualifications than the others, and the people would gradually become used to the distinction, and employ by preference those whom they knew to be better prepared to treat disease.

Periurethritis Dissecans as a Complication of Gonorrhœa.—Dr. Matlakowski, of Warsaw, details the following instance of what he appropriately calls *periurethritis dissecans.* A man, aged forty-eight, had contracted gonorrhœa, presenting no unusual features except a strikingly profuse purulent discharge. Notwithstanding an assiduous treatment by injections (of some "mild solutions"), the penis had soon become swollen, hard, and moderately painful and tender, while there had supervened inflammation of the dorsal lymphatics and continuous erections. On examination by Dr. Matlakowski, about five weeks since the first symptoms, the patient's member was found to be enormously enlarged, knotty, hard, tense, erect, and hot, the orifice profusely discharging ropy pus, the prepuce slightly tumefied, the site of the urethra occupied by fluctuating swelling reaching from the glans down to the scrotum, the inguinal glands somewhat enlarged. The micturition, however, was free, and the bodily temperature normal. Having without delay brought the patient under the influence of chloroform, the author made an incision eight centimetres long, running along the urethra on the lower aspect of the penis. A large quantity of pus escaped from the wound, after which it became evident that the urethral tube was completely detached both from the integuments and cavernous bodies, and was lying quite free in the purulent cavity, from which it could be easily drawn out through the incision by means of a probe. A digital examination showed that suppuration had extended backward to the foremost scrotal tissues, and separated the cavernous bodies of the penis. The latter structures themselves, however, as well as the urethral cavernous body, had remained quite intact. The wound rapidly healed, except one spot, where there formed a minute urethral fistula, discharging a few droplets of urine on micturition. Dr. Matlakowski adds that he has been unable to find another similar case in international literature.—*The Provincial Medical Journal, February* 1, 1890.

Tongue-tie.—Dr. Tassius, of Berlin, makes himself responsible for some novel views on the propriety or otherwise of incising the frænum of the tongue. He says in his introductory remarks that the little operation has often been performed without considering that other and deeper causes, especially those connected with the general development, may be accountable for the faulty development of speech than the mere size of the frænum. He considers that this tiny and admirably constructed organ is a correct regulator of the various movements of the tongue,

and that, if the same be too hastily interfered with, the more delicate movements may be forever destroyed—a momentous fact for those who are destined to become public singers. He advises his medical brethren, therefore, to proceed very cautiously, and not to operate at too early an age, as much improvement may result from the advancement of general development. Only in those cases in which the frænum is so abnormally large and tendinous as to cause a fissure in the tip of the tongue, may the incision be made at once, but it should be calculated almost mathematically what proportion the depth of incision should bear to the fissure. The author deprecates, therefore, the use of scissors, as not to be depended on, but advocates the employment of a small knife, the incision to be made from below upward. Where the frænum is of a fleshy character, and it is, consequently, certain that the child will never gain distinction in singing or elocution, there is, according to Dr. Tassius, no cause at all for immediate interference, unless the deformity causes a real impediment. It is far better to leave such cases—at any rate for some time—entirely to the *vis medicatrix naturæ*.—*The Lancet.*

Table for the Differential Diagnosis of Gastric Affections.—Dr. Loundby has prepared the following table as an aid in the diagnosis of diseases of the stomach :

Symptoms.	Gastrodynia.	Atonic Dyspepsia.	Gastric Catarrh.	Ulcer.	Cancer.
Character of Pain.....	Dull, heavy.	Dull, heavy.	Burning soreness.	Acute stabbing.	Cutting.
Locality	Epigastrium.	Epigastrium.	Behind sternum.	In one spot.	Epigastrium.
Incidence.....	Immediately.	After 1 or 2 hours.	After 2 or 3 hours.	Immediately.	After 1 or 2 hours.
Tenderness ...	Sometimes.	None.	None.	Usually.	Usually.
Vomiting.....	Usually.	None.	Often some retching.	Usually.	Usually.
Hæmatemesis.	None.	None.	None.	Usually.	Usually.
Tongue.....	Clean.	Clean.	Furred.	Clean.	Variable.
Tumor.....	None.	None.	None.	None.	Usually.
Age	Usually under 30.	Any age.	Any age.	Usually under 30.	Usually over 40.
Sex	Usually female.	Either.	Either.	Usually female.	Usually male.

Successful Removal of a Knife from the Bladder.—At a recent meeting of the National Academy of Medicine of Mexico, Dr. Lavista related the following case. A man about thirty-five years of age received a stab in the abdomen which penetrated the bladder. The man, who was on horseback at the time, made the animal rear when he felt himself wounded, and the blade of the knife was broken over the pubic bone, one of the fragments falling into the bladder, where it remained for two years and a half. The wound gradually closed, but the foreign body set up severe cystitis, and from the time of the injury the patient was never able to hold his body quite straight—it was always bent a little forward. He suffered such incessant pain that he could hardly sleep, and he became greatly emaciated. Calculus having been diagnosed, lithotrity was attempted, but it was found impossible to crush the stone. An exploratory opening was then made through the perineum, when the knife was discovered "placed like a bridge between the two walls—anterior and posterior—of the bladder, directed obliquely downward and backward, the edge being undermost." It was so immovably fixed in this position that it was impossible to remove it through the perineum. Supra-pubic cystotomy was then performed, an incision five inches in length being made. Even this was not sufficient, and the wound had to be enlarged. The knife was at last got out, and then the fragments of a large stone, which had distended the bladder, and in this manner had prevented the point of the knife from penetrating its wall, were removed. The walls of the bladder were ulcerated and covered with vegetations. After scraping the mucous membrane, the wound of the bladder-wall was accurately sutured, provision being made for drainage both above the pubes and through the perineum. "Healing was almost immediate, no untoward circumstance occurred, and the course of the case has been of the happiest." One hardly knows which most to admire in this extraordinary case, the skill of the surgeon or the phenomenal endurance of the patient.—*The London Medical Recorder.*

Surgeon Parke.—A *Times* correspondent, in the report of an interview with Mr. H. M. Stanley, at Suez, thus refers to Surgeon Parke : Dr. Parke, another old friend of all Anglo-Egyptians, was then still clothed in the white drills in which he had crossed Africa. Pulled down by recent fever, his color just returning with the sea voyage, he looked younger than when he started, and it seemed incredible that he should be the man to whose unceasing work and skill Mr. Stanley bears such willing testimony. By one trait he will be recognized, however, by all who have ever met him. "He spoke to every woman in the interior of Africa with the same gentleness and courtesy as he would to a lady in a drawing-room at home," said Mr. Stanley.

Antisepsis in Wood-working.—There appears to be such a thing as a diagnosis of disease in wood. Dry rot is called contagious, and it is said that the germ of that disease may be communicated to sound wood by tools which have been at work in diseased wood. It is thought possibly that the theory accounts for many otherwise incomprehensible breakages of timber. The suggestion is that sound timber should not be cut with the saw that has passed through wood affected by dry rot without cleaning.—*American Druggist.*

The Advantages of a Sea Voyage.—The benefit to health following upon a sea voyage is, according to Dr. Burney Yeo, due to the following causes : 1. Perfect rest and quiet, a thorough change of scene, and perfect and enforced rest from both mental and physical labor. 2. The life in the open air, and the great amount of sunshine enjoyed, it being quite possible to spend fifteen hours every day in the open air. 3. The purity of the sea-air, no organic dust or impurities—the air of the open sea being the purest found anywhere. 4. The great humidity of the atmosphere and the high barometric pressure, which are considered to exercise a useful sedative influence on certain constitutions. 5. The exhilarating and tonic effects of rapid motion through the air—the sea-breezes are constantly blowing over the ship. These breezes increase evaporation from the skin, and impart tone to the superficial blood-vessels.—*The Nineteenth Century.*

The Difference Between a Lawyer and a Doctor.—What, under the laws of Kansas, is the difference between lawyers and doctors? The lawyer gets his fee if he wins his case, the doctor if he loses it. When the lawyer wins his case he may file a lien upon the judgment for his fees, if he loses it he must trust to the honor of his client. If the doctor loses his patient his fee is a preferred claim, if he cures him only the few who have, in their own name, more than the law exempts, are compelled to pay his bill.—*Kansas Medical Journal.*

Transmission of Phthisis in Married Life.—M. Leudet has occupied himself with collecting some statistics on the question of whether a wife can give phthisis to her husband, or a husband to his wife. He has taken 112 widows or widowers, whose husbands or wives respectively have died in undoubted phthisis. Out of these 7 were phthisical ; but several of them had facts in their previous history, before marriage, showing a phthisical tendency. His inference was, therefore, that the transmission of phthisis in married life must be very rare ; even more rare in the upper classes than in the middle and lower. In 80 out of these 112 cases there was a family history which he could follow ; and 27 of these showed some members who were phthisical.—*The Practitioner*, February, 1890.

A Medical Delegate.—Dr. Montague, of Haldimand County, Ontario, has just been elected a member of the Ontario Parliament.

ON THE RESULTS OF TREATMENT OF FRACTURE OF THE PATELLA WITHOUT OPERATION.[1]

BY WILLIAM T. BULL, M.D.,

PROFESSOR OF SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS; SURGEON TO THE NEW YORK HOSPITAL.

BEFORE the spread of antiseptic surgery there was a general agreement as to the results of fracture of the patella. Bony union was regarded as a great rarity, and efforts were directed to obtaining as short and firm a ligamentous union as possible. Anchylosis was much feared, and the use of passive motion at an early period in the treatment was general. With antisepsis bony union was attained, and at the outset it seemed that we had made a great gain; but the danger of the operative procedure soon became apparent, and it may be said to be in disfavor. But it has had a voluminous literature, in glancing through which one is struck by the fact that, in the opinion of operators, the chief indication for operation is the fact that with the old methods not only bony union but useful limbs, were exceptional. Hamilton [2] was one of the first to make a large collection of cases (127) treated without operation. His example has been followed by Beck,[3] who gives the results of sixteen years' experience, at the Tübingen clinic, of both operative and mechanical treatment; and Brunner [4] has done the same with all cases at the Zürich clinic for twenty-five years. As a further contribution to the results of non-operative treatment, I present what I can glean from my own experience for the past fifteen years. I am able to report on the result in twenty-two cases after periods varying from one year and nine months to thirteen years after the date of injury. I have records of twenty-two other cases. In the majority of these the condition has not been noted after leaving hospital at the end of treatment taking about six or eight weeks. Although the hospital notes give evidence that the ligament was as a rule short and the patients able to extend the limb, there has always been noted more or less stiffness on flexion. I can therefore make no use of those cases which careful search has failed to find since leaving hospital, and ask your attention only to those in which the result has been seen after a period exceeding one year from the end of the treatment. It is generally conceded by authorities that the restoration of function to the knee is slow, varying from six months to a year; and it is useless to frame convictions on results reported at an earlier period. Stimson, in writing of bony union, says: "The test is found in time and use, and it is quite common to see a gap, which is very slight at the time treatment ends, increase to the length of half an inch or more in the course of a few months." [5] This is quite as true of the result of ligamentous union.

These cases, excepting one, have been examined by Dr. C. A. Powers or myself within the past two months.

The above twenty-two cases embrace sixteen in which the injury was a primary fracture, and six cases of "refracture." But nineteen patients are represented, as three had had fractures on both sides at different times. Inasmuch as the functional results are not to be expected to be so good in the cases of "refracture" or rupture of the ligamentous union, I will speak separately of them. Of the sixteen fractures, I find an excellent result in fourteen, a bad result in two. In round numbers eighty-seven and a half per cent. are satisfactory; twelve and a half per cent. are unsatisfactory.

Let me go more into details as regards the functions of the limb, to explain what I characterize a good result. Where flexion and extension of the limb have been complete and strong, and the ligament firm, with little or no atrophy of the thigh, the result may be summed up as "functionally perfect." There are ten such cases. Where either flexion or extension has been imperfectly performed, with, however, a joint useful, according to the patient's statement, for all the purposes of his or her occupation and exhibiting weakness only after unusual exertion, the result has still been called "good." There are four such cases. The bad results embrace two cases in which there is no power of extension whatever, and the patients are compelled to wear supports or walk with a cane.

In order to make these statements clearer, let me abstract some details from the histories which are appended to this paper. The following are the conditions in the fourteen cases which I consider attended with good result (the length of the ligament is given in the flexed position):

1. Functions perfect at end of ten years and two months; ligament, $\frac{1}{4}$ to $\frac{1}{2}$ inch; no atrophy. 2. Functions perfect at end of twelve years and five months; bony union; no atrophy. 3. Functions perfect at end of thirteen years; ligament, $\frac{3}{4}$ inch; atrophy, 1 inch (at end of eighth month this ligament was recorded as two inches in length). 4. Functions perfect at end of eight years and six months; ligament, $\frac{1}{4}$ inch; no atrophy. 5. Functions perfect at end of five years and five months; ligament, $1\frac{1}{4}$ inch; no atrophy. 6. Functions perfect at end of five years and six months; ligament, $1\frac{1}{4}$ inch. 7. Functions perfect at end of five years and two months; ligament, 1 inch; no atrophy. 11. Functions perfect at end of one year and nine months; ligament, 1 inch; 2 inches atrophy. 10. Except flexion, which is eighty degrees; functions perfect at end of two years and one month; no separation; $1\frac{1}{2}$ inch atrophy. The patient is a waiter by occupation; is sure that the limb is as strong and as serviceable as ever. 8. Flexion ninety degrees; extension a trifle short at end of three years and one month; ligament, 1 inch. 9. Movements free, but limb is weak after unusual exertion; cannot run far. At end of one year and two months no separation of fragments. 13 Functions perfect after ten years and eight months; ligament, $\frac{1}{4}$ inch. 18. Functions perfect after six years; ligament, $1\frac{1}{4}$ inch. 15. Died five and one-half years after leaving the hospital. Her friends, living in the same tenement-house, state that she walked up and down stairs without limp or assistance, and worked hard without complaint.

The occupations of these people are sufficiently laborious to test the usefulness of their limbs; all but one (Case 11, a lawyer) belong to the class that work either in their homes or at their various occupations. One is a policeman on active duty in the Sixth Precinct; another, an assistant foreman in the city's fire department. In detail, the occupations are as follows: 1 lawyer, 1 policeman, 2 firemen, 2 drivers, 4 housekeepers, 1 waiter, 2 laborers, and one not stated. There are 4 women, aged

respectively, twenty-five, twenty-eight, forty, and fifty-five; and 10 men, 5 of whom were from twenty to thirty years old at the time of accident, 3 from thirty to forty, and 2 from forty to fifty.

One may say roughly, that three-fourths were between the ages of twenty and forty.

Looking at the condition of the union, we find it bony in one instance; in two it is described as "No appreciable separation of fragments;" while in the ten remaining cases the shortest is one-fourth of an inch, the longest one and one-fourth inch, the average nine-tenths of an inch.

This corroborates the statement usually made that a ligament from one-half to an inch in length permits the functions of the joint to be perfectly executed. Several cases bear witness that a firm ligament may be formed and undergo but trifling elongation in the course of years.

Thus in Case 1 ligament measured one-fourth inch at end of six months, and the same at the end of ten years.

In Case 5 ligament was one-fourth inch long at end of six weeks; one-half inch long at end of five years and five months.

In Case 6 ligament was one fourth inch long at end of six weeks; one-half inch long at the end of five years and six months.

In Case 7 ligament was one-fourth inch long at end of seven weeks; one-third inch long at end of five years and two months.

In Case 8 ligament was ½ inch long at end of ten weeks; 1 inch long at end of three years and one month.

One patient, Case 3, after a lapse of thirteen years, shows a shortening of the ligament from two inches to three-fourths of an inch. This is doubtless due to the formation of bone in the band, an instance of which is mentioned in Hamilton's book (7th edition), page 549. Of the length of time which elapsed before the joint reached a maximum of improvement, I have no record; and can only give the general impression, gained from having seen some of these patients from time to time, that this period would be from six or eight months up to one year.

In the two cases attended with what I call bad or unsatisfactory results, there is recorded:

Case XII.—Extension incomplete; joint weak; no anchylosis. "Backs" down-stairs; at end of six years and eight months ligament one and one-half inch.

Case XIV.—Joint very weak; at end of eighteen months ligament one-fourth to one-fifth inch (on leaving hospital, there was thought to be bony union). The six cases (16, 17, 19, 20, 21 and 22) which experienced a subsequent rupture of the ligamentous union, are twenty-seven per cent. of the entire number. The accident occurred, in three of the cases, within two months after discharge from the hospital; in two others, at eleven months and one year; in one, ten years. One patient met with a second refracture after an interval of five years. In one instance (Case 20) there is noted a fracture of the lower fragment while the ligamentous union remained intact. This was also the case in one of the three cases of ruptured ligament, found among the twenty-two cases not traced after leaving hospital. This giving way of the bone instead of the ligament has been noticed by many surgeons, but we are not able to say in what proportion of cases it occurs. The results in two of these "refractured" cases were surprisingly good.

Case 20, after two "refractures," was examined seven years after the last accident and found to make flexion and extension completely and strongly, with a ligamentous union of one inch (the other patella is Case 21).

Case 22, had complete functions after eleven years, with a ligament three and one-fourth inches long and atrophy of thigh equal to one and one-half inch; works as a truckman without fatigue.

The four remaining cases lack the power of extension. Three have ligaments 1¼, 5, and 2½ inches respectively; in one the length of the ligament was not noted. One walks with a cane and two wear some support. All complain of weakness. But one has decided stiffness of the joint. Atrophy of the thigh is noted in all.

Neither the age of the patients nor the cause of the fracture, direct violence or muscular action, seem to have had any influence in the result. Of the nineteen patients, three had subsequent fractures of the other patella after intervals of one, five, and ten years respectively.

From the above details it would appear that it is possible to get a satisfactory result in about eight of every ten cases of fractured patella by the use of simple retentive apparatus, provided no accident endangers the safety of the newly formed ligament. But as the so-called "refractures" are considered by many as an accident, to which the primary fracture predisposes, it may be fairer to interpret these statistics in a different way. There are nineteen patients who had fractured patella. If we consider the refractures as part of the history of the primary accident, we have from nineteen patients fourteen good results, two of which are after refracture, and five bad results, four following that accident. By allowing, then, for the accident of refracture, we get a much less favorable percentage, still a good one, of satisfactory results—73 per cent., or nearly three-fourths of all cases.

This refinement of statistics seems to me of little value, however, for some cases have been followed for much longer periods than others, and we cannot tell what is to be the fate, in regard to refracture, of those who have been observed for but short periods. It is enough to know that this accident is a frequent one, and that its prevention is a matter of importance in the treatment.

Although, as I have already mentioned, there are numerous instances where one of the fragments has fractured instead of the ligament rupturing, it does not seem to me at the present at all proven that the ligamentous is as strong as the bony union On the other hand, it may be averred that the ligament is strong enough for all practical purposes—since many patients meet with no rupture.

In all these cases the treatment has been practically the same that was in vogue in Bellevue Hospital when I was interne there in 1872. It consists in the use of plaster-of-Paris bandages after the effusion has subsided, with the application beneath the splint of adhesive plaster strip to steady the fragments. If the patient has been seen immediately after the accident, ice-bags or cold water compresses have been applied to the knee, after a posterior splint of wood, felt, or pasteboard (and in hospital always of tin or iron, the Volkmann's splint with footboard) has been fitted to the limb. If seen several hours after injury I have discarded the use of cold or evaporating lotions, especially the lead and opium wash, which is ruinous to linen, and relied on equable compression of the joint, with cotton compresses and snug bandages, to promote absorption of the effusion; the limb has been slightly elevated on pillows. The diminution in swelling, has permitted the approximation of fragments after periods varying from two days to two weeks; on the average I should call it the fourth or fifth day. When the gypsum bandage is applied, the limb has been elevated and the upper fragment has been drawn down and held by the loop of plaster, the centre of which rests above it on a pad of lint or gauze, while the ends pass obliquely downward to the upper part of the calf and the posterior surface of the leg. The lower fragment is similarly supported. It is possible to tilt the fragments by this manœuvre and so separate their upper margins. Their position should be noted and the first turns of the muslin or flannel bandage, which protects the skin from the gypsum, should be passed circularly about the centre of the knee, to counteract this tendency to tilt. I believe the plaster strips are not necessary, and that one could accomplish quite as much by simply using the "figure-of-eight" turns of a bandage. After the tendency to effusion has subsided, there is no tendency to drawing up of the fragments. The patient sits up after the gypsum splint is dry; if there be much shrinkage of the limb and the splint gets loose, it may be renewed. After six or eight weeks it has

been removed. and its posterior half or another hard splint of leather is applied and the patient allowed to walk. I have sometimes allowed them to walk with crutches after the fifth week; and it has seemed an advantage to have the first efforts at walking made a few days before the gypsum splint has been removed. For the next month or six weeks the posterior splint has been always worn by day; the thigh and knee vigorously shampooed and kneaded; but care has been taken not to make motion to flex the joint and thereby stretch the ligament. Electricity may be used if there is much atrophy of the thigh. At this period (end of three months) I have usually found patients able to bend the limb but slightly—say not quite to forty-five degrees from the straight position, but the power of extension has been good. Occasionally, in weak or nervous patients, the splint has been used for an additional month—making the period of enforced stiffness four months.

From this point the treatment has been merely the exercise of care to avoid accident and, by gradually increasing the work of the limb, to permit the functions to be restored. I have generally advised patients to use a cane during all this period, partly to remind them to be careful and partly to aid them in case of misstep; and have suggested the occasional use of a short splint behind the knee when any extra exertion was to be made; but I have learned to discourage the use of any kind of bandages or knee-caps after this period, and permitted their application, as in the case of the splint, only at odd times as a "reminder." It has been often necessary to urge patients not to favor the injured knee in the ordinary use of it. Passive motion I have rarely recommended and, with most surgeons, I believe it unadvisable. In one of the reported cases it produced a refracture, and it would be an exceptional case in which it would be indicated.

In Case 1, at the end of four months, the ligament was short and strong and the extension complete, but the woman was timid and would not make proper use of the joint, and flexion was imperfect. I advised forcible bending in vain, but at a religious feast she was commanded to kneel down, and did so, snapping the light intra-articular adhesions and giving perfect freedom of movement.

The daily use of the limb, with friction of the knee at night, and no more forcible measures than the effort to bend the knee while the foot is on the floor—an exercise which should be practised daily, are quite sufficient to restore the functions in the majority of cases. There are no accidents to be expected from this treatment in the hands of even the least experienced practitioners. In but one case of the entire number has there been any reaction from the pressure of the splint; then a fenestrum was cut and the effusion found to have returned. It promptly subsided. There is no objection to cutting a fenestrum, or trap, in every splint a day or two after its application, and I would advise it if one has not constant experience in using plaster bandages. I have no doubt the use of any other coaptable material would give as good results, and I would expect to accomplish as much with felt, or leather, or hat-lining. But the gypsum is the easiest and most convenient to handle, and I can conceive no possible objection to its use. Some surgeons still adhere to the idea that it causes atrophy and may make pressure dangerous to the circulation, and are opposed to its use in general. These objections do not hold in the application to this fracture; it is not recommended until the swelling has subsided, it is always preceded by a layer of cotton and muslin bandage, and the inexperienced doctor, or one at a distance from his patients, may insure against accident by cutting down the splint before it has fairly set, or making a trap door.

The treatment after this manner lasts about six months, but involves a period of rest and confinement for only six weeks. A second period of six weeks can be spent in any kind of occupation or amusement that can be carried on with a knee stiffened with a ham splint. During the following three months much care must be exercised to prevent accidents, and this may entail loss of time or money in the case of those who pursue arduous occupations. But I do not think the period of treatment can be advantageously shortened; and I feel confident that the number of good results in my cases would have been larger if all the patients had been advised at frequent intervals during the six months' treatment. I am not, however, so confident as to overlook the fact that the results might be better. Between the sixth and the ninth months the patient should be steadily gaining. If there be a marked atrophy of the thigh, without much separation of fragments, the development of the quadriceps should be stimulated to the utmost. If the ligament and joint functions begin to weaken I should advise wiring the bone; if done at this period the operation would be easier than when, at a later time, the fragments are wider apart. For stiffness I should hesitate to interfere. Better a strong and stiff joint than a weak and limber one. It would be rare to find a case which could not be flexed enough to keep the foot out of the way in sitting down. But if such stiffness existed with impaired extension, I should break up the adhesions first and afterward wire the fragments.

The treatment of rupture of ligamentous union should be a conservative one until it is apparent that the result is to be unsatisfactory, when it may be wired. I have operated on one such case about six weeks after the first fracture. The result was bony union, with flexion to ninety degrees, but complete power of extension. At the end of two and a half years, however, the patient complains of weakness of the limb, and there is atrophy of the thigh (one inch).

Case 22, refracture after six months, treated conservatively, with a ligament of three and a half inches, has a limb quite as useful at the end of eleven years. In view of the many defective results after wiring for refracture, and the accidents that have followed the operation in general, and further, from the numerous instances of fairly useful limbs with long ligaments, I should only urge the operation in a very promising case, and with the patient's knowledge of its risks and uncertainties. The same may be said of old ununited fractures. The only case I have treated was operated upon with fatal result (Case III., p. 318). Where no operation is undertaken, an apparatus may be worn to provide for the motion of extension.

In compound fractures there is no question as to the propriety of wiring. The only case I have to record was operated upon in 1882; result, death from septicæmia (Case II., p. 318). The fracture was comminuted.

Although my experience has been limited in recent fractures to the simplest conservative treatment, it will not be out of place for me to offer some criticisms on the more severe operative procedures which have attracted so much attention. First, of wiring the patella. it is needless to say that, while it made its entrance into practice by the advocacy of the pioneer in antiseptic surgery, Sir Joseph Lister, it has never received general support. One does not need to quote the discussions of the French Société de Chirurgie, or of the Medical Society of London, where the majority of speakers opposed it; nor to be familiar with the collection of statistics which speak against it—one of the most complete of which, Dennis [1] has given to the profession of this city; it is sufficient to know that death and disaster from amputation and suppuration and anchylosis have followed its performance in the hands of the many, and that we have no evidence that when, in the hands of the few it has proven safe, the ultimate results have been better than those by non-operative methods.

It is sufficient to condemn it that its advocates admit that its "success depends upon carrying out the smallest detail, and that it should never be undertaken by an ordinary practitioner." [2] But it is furthermore of interest to know that when its results are compared with those of

[1] New York Medical Journal, April 3, 1886.
[2] Quoted from Dennis's paper (1886).

the conservative treatment, all the cases being in one hospital, the judgment of an experienced surgeon is against it. It is not necessary to go into details. I will merely quote the conclusion of Brunner, after narrating the experience of the Zurich clinic for twenty-three years: "The previously adopted bloodless methods are appropriate, and the suture by operation of a fresh fracture of the patella is only justifiable when it is compound." [1]

I believe that there are some surgeons active in this city, who practise in recent cases the operation, and I beg, if any of them are present, that they will explain by what process of reasoning they can call it a justifiable procedure.

But there are other methods at present in vogue, to which the name operative may be correctly applied, since they necessitate a wound. Schede proposed to hasten the approximation of the fragments by puncture and irrigation of the joint. Aspiration has also been suggested. There are no accidents recorded from these procedures, but they have often failed to accomplish the purpose. I punctured the joint with an aspirating needle in two cases which presented a rapid reaccumulation. When a trocar has been used the joint cavity has been found to contain so much blood that incision and thorough washing were found necessary; and this has been rightly considered almost as serious an operation as wiring.

Efforts to bring the fragments together by subcutaneous suture of silver wire, proposed by Volkmann, and modified by Kocher, who called it the "peri-patellar suture" have not been happy in their results. Brunner gives seven cases of Kocher's method, with one death, one subsequent operation of wiring because of suppuration, and in the remaining cases which had no reaction there was but one bony union. This peri-patellar suture, with silk instead of wire, has been used in the New York Hospital by two of my colleagues, who, I hope, may be able to give a good account of it. I have seen one case where suppuration ensued, with the most threatening septic symptoms, and the end was a stiff joint. Malgaigne's hooks have been used with and without the protection of antiseptic dressings. Mr. Treves, of London, speaks favorably of their use, though he offers no cases in evidence. They have been modified by Levis, of Philadelphia, and Otis, of this city, but we have no reports that give any idea of the ultimate result—no evidence that anything has been gained by their use. I look upon all these procedures as unnecessarily complicated. They aim to get bony union, but they are attended with risk; if they are adopted it must be in the face of evidence that ligamentous union will give a useful and strong limb, and that this can be accomplished by safe and simple measures.

A. Cases of Fracture of Patella treated without Operation.—Case I.—F——, a seamstress, aged forty, weighing over two hundred pounds, with transverse fracture of left patella from falling down stairs, December 16, 1879. No treatment for three hours—one-half inch separation—moderate swelling. Gypsum splints over adhesive plaster retention strips. Bandage renewed once in six weeks; removed at end of six weeks. Ligamentous union, one-eighth inch separation. Flexion to forty-five degrees. Short posterior leather splint for five weeks more. Movement increased. End of fourth month, flexion to ninety degrees and extension perfect. Gentle passive motion recommended, but declined. Flexion suddenly increased by an effort to kneel at a religious feast. Sixth month, motions full, free, and strong, and no fatigue experienced except in using sewing-machine. Separation from one-fourth to one-half inch. End of ten years and two months, condition unchanged; but ligament a trifle longer. All joint functions satisfactory. No atrophy. Physician, Dr. J. B. Anway.

Case II.—S——, fireman, aged twenty-seven, fell, striking knee, September 4, 1877. Transverse fracture of right patella with one-inch separation and considerable effusion. Posterior splint, compression with cotton and bandage for four days, then fenestrated gypsum splint over retention strips of adhesive plaster for six weeks, followed by short posterior splint for six weeks more, with massage. Condition at this date not noted. At end of twelve years and five months is active member of the fire department. No difference in circumference of limbs, function of knee perfect, and no appreciable separation of fragments—a bony ridge existing at site of fracture. Chambers Street Hospital. Nine cases (II., III., IV., V., VIII., X., XIV., XIX., XXII.) were exhibited before the section.

Case III.—D——, a policeman, aged twenty-four, struck knee in falling, February 19, 1877. Transverse fracture of left patella with moderate effusion. Same treatment as above. At end of eight months it was noted: "Functions perfect; separation of one-half inch in extension and two inches in flexion."

At end of thirteen years, a firm ligament, three-fourths of an inch in length, both on flexion and extension. Circumference of thigh at middle, one inch less than right. Functions perfect. Weight, over two hundred pounds. On active police duty, and finds the limb as serviceable as its fellow for all purposes. Chambers Street Hospital.

Case IV.—A——, hack-driver, aged thirty-nine, fell from wagon on knee, May 24, 1881. Transverse fracture of right patella at middle. Treated for six weeks with gypsum splint over retention strips of adhesive plaster and elastic webbing. Walking with posterior splint for four weeks more. At end of eight and a half years the joint functions are found perfect, no atrophy, the limb quite as useful as the other. Separation, three-fourths of an inch.

Case V.—B——, male, aged twenty-three, fell on the knee thirty hours before admission, June 9, 1880. Transverse fracture of left patella at junction of middle and lower thirds. Gypsum splint seventh day. Discharged at end of six weeks, walking well, with one-fourth inch separation. Nine years and five months later: "Functions perfect; no difference in measurement of legs; in extension, separation of one-half inch; in flexion, one and one-fourth inch."

Case VI.—S——. a housekeeper, aged twenty-five, fell, striking on knee, March 11, 1884. Transverse fracture of right patella with separation of one inch and slight effusion. Posterior splint and compression with bandage. Three days later, plaster splint with adhesive straps. At end of six weeks discharged, walking with posterior splint; separation one-fourth inch. At end of five and a half years: joint functions free and strong; separation of fragments in extension, one-half inch; in flexion, one and one-fourth inch.

Case VII.—M——, male, aged thirty-eight, felt knee "give way" while lifting, July 23, 1884. Transverse fracture of left patella at middle, with two and one-half inches separation and much effusion. Gypsum splint in forty-eight hours. Discharged, with posterior splint at end of seven weeks. Separation, one-fourth of an inch. Examined five years and two months later: Functions perfect; no atrophy; separation, one-third of an inch in extension and one inch in flexion.

Case VIII.—S——, a driver, aged twenty-six, fell from wagon, striking on right knee, August 8, 1886. Transverse fracture of lower from upper two-thirds of patella. Same treatment as above. Gypsum splint on eighth day. Discharged at tenth week, wearing posterior splint, with one-half inch separation. Condition noted at end of three years and one month: Extension a few degrees short of being complete, with separation of one inch; flexion to ninety degrees only, with two and one-half inches separation. Leg not perceptibly weaker, than other. Can go up and down-stairs readily, but has to move injured leg rapidly. Two weeks after leaving hospital strained the joint, which was then kept in splint for three weeks.

Case IX.—H——, housekeeper, aged twenty-eight, fell down "doubling" knee under her, six hours before admission to hospital, August 14, 1888. Transverse

[1] Deutsche Zeitschrift f. Chir., 23.

fracture of right patella, at middle; separation of three-fourths of an inch. Splint at end of two weeks; removed at end of nine weeks; discharged at end of tenth week. At end of one year and two months there is no appreciable separation of fragments, and movements are free, but she cannot run fast, and knee feels weak after going up several flights of stairs. Had diabetes mellitus at time of accident.

Case X.—D——, male, aged forty-five, struck knee on pavement, September 2, 1887. Transverse fracture of left patella. Seventh day, gypsum splint. At end of two years and one month "there is a depression felt running transversely across middle of patella, but no appreciable separation. Extension complete; flexion to eighty degrees; thigh, one and one-half inch less in circumference. He is sure that the limb is just as strong and as serviceable as ever." New York Hospital.

Case XI.—R——, a student, about twenty-two years of age, who had made a creditable record as a high jumper in college athletics, fell on the right knee at Cedarhurst, May 12, 1888. At New York Hospital, a few hours later, he was found to have sustained a transverse fracture of patella, the lower third being separated by a slight interval. Effusion moderate, so that the following day a gypsum splint was applied, and he was transferred to his home on Staten Island in care of Dr. Carroll, of New Brighton. Second splint, a week later; worn five weeks, and replaced by "Tiemann's knee brace," which was worn five or six weeks while the patient made a voyage to Europe. The functions of the limb returned slowly. Six months later the union was by a short ligament; motions were free, but extension not so strong as on the sound side. The thighs were, before the accident, a marvel of muscular development owing to his frequent exercise. Examined, one year and nine months after injury, there is found a firm ligament less than one-half inch long. The right thigh is one half inch less in circumference than the left. The motions are free and as strong as ever, so he avers; he can run and dance, though he has not attempted jumping.

Cases XII. and XIII.—H——, male, aged thirty-eight, broke left patella at its middle, transversely, in getting out of wagon, March 29, 1883. Third day, gypsum splint; sixth week, discharged with posterior splint. At end of six years and eight months the joint is weak. He has to go down-stairs backward. No anchylosis. Extension not complete (155 degrees). Ligament in extension, three-fourths of an inch; flexion, one and one-half inch. Chambers Street Hospital. The left patella was fractured ten years and eight months previous to examination by Dr. Powers; treated by the late Dr. F. H. Hamilton. This limb is functionally perfect; the fragments united by a strong band one-fourth of an inch in length.

Case XIV.—R——, male, aged thirty, direct violence (an iron gate fell across knee), July 20, 1880. Transverse fracture of right patella, lower fragment very small. Second day, gypsum splint; at end of six weeks, no separation. Union thought to be bony. At end of eighteen months, there was "a separation of one and one-half inch on extension, and four or five inches on flexion, and the joint is very weak." Chambers Street Hospital.

Case XV.—McG——, female, aged fifty-five, fell on knee, May 20, 1884, fracturing right patella transversely. Gypsum splint on eighth day and posterior splint at end of six weeks. Died five and one-half years later. Her friends say that she walked well, up and down-stairs, without limp or assistance. New York Hospital.

Case XVI.—H——, male, aged forty, refractured right patella, June 4, 1887. The previous fracture was in 1877. Next day, gypsum splint, in which fenestrum was cut twenty-four hours later, to apply evaporating lotion. Discharged in six weeks. At end of two and one-half years, fragments are separated by ligament one and one-half inch long; thigh very much atrophied; no power of extension, and flexion limited by stiffness which has persisted since he left hospital; obliged to wear heavy anterior brace. New York Hospital.

Case XVII.—N——, male, aged forty-five. fell on knee, February 10, 1885, sustaining transverse fracture of left patella at middle. Gypsum splint fourth day. Examined four years later; has no power of extension; obliged to wear splint; apparently no ligament exists, and fragments are five and one-half inches apart on flexion. Thigh at its middle is three-fourths of an inch, at its lower third one and one-half of an inch less than the right, and the calf is one inch less in circumference than the other. He says that two months after discharge from hospital he slipped and strained the knee and cracked the posterior splint. He continued to walk with a splint and had no treatment.

Case XVIII.—His right patella was fractured six years ago. He was treated at Bellevue Hospital with gypsum splint. The functions of the knee are now perfectly performed. There is a firm ligament three-fourths of an inch long on extension, one and one-fourth inch long on flexion, and the limb is strong.

Case XIX.—C——, male, aged forty, fell on knee October 23, 1881. Transverse fracture of right patella. Gypsum splint on the ninth day. Seventh week, discharged with posterior splint; separation, five-eighths of an inch. One month later, strained knee and fragments separated. Has walked with cane ever since. At end of eight years, atrophy of thigh two inches; no anchylosis; extension to a little beyond a right angle. New York Hospital.

Cases XX. and XXI.—C——, housekeeper, aged twenty-three, fell on right knee, January 10, 1878, refracturing right patella, which had been broken about a year previously. The ligamentous band of the previous fracture was found intact, and the lower fragment broken transversely at its middle, with but slight separation of the fragments. Treated with gypsum splint for seven weeks. The functions of the joint were gradually regained. Five years later she experienced a third fracture or rupture of the ligament, which was treated again with gypsum splint. Of this there is no record. But at the present date, twelve years from the first, and seven years after the last fracture, the functions of the joint are found to be practically perfect. The ligament is strong and only one inch long on flexion. There is no trace of the ligamentous union of the fragments of the lower half which was detected at the time of the second fracture. No comparison can be made with the other limb, for the left patella was broken about five years ago. She was treated with gypsum bandage in hospital. The only record of result is that on discharge one could "lay little finger between the fragments." Two months after discharge she ruptured the ligament while going up-stairs, and was treated at home. After removing the splint there was stiffness, for which passive motion was made by her physician. During one effort, according to her account, the ligament was severely strained. Now the left knee is decidedly weak. Extension is imperfectly performed, the ligament is two and one-half inches long in flexion.

Case XXII.—H——, male, aged twenty-nine, kicked by horse, March 12, 1878. Transverse fracture of right patella. Gypsum splint fourth day. Discharged six weeks later with posterior splint. He says the limb was as strong as ever six months afterward. February 5, 1879, ruptured the ligament. Same treatment. At end of eleven years there is found a ligament three and one-half inches long on flexion, an atrophy one and one-half inch of thigh, and one-half inch of calf. Walks up and down-stairs easily, and works as truckman without fatigue, but favors the injured limb in making unusual exertion.

B. Cases of Compound and Ununited Fracture of Patella Treated by Suture.—Case I.—S——, male, aged thirty-two, fractured right patella four months before admission to New York Hospital, March 30, 1887. Walked without any splint at end of ten weeks. Refractured two weeks later. On admission, four weeks after last accident, and four months from date of fracture, he has "weakness" in the joint, there is a separation of one inch, and the power of extension is greatly diminished. There

is fluid effusion in the joint, and one and one-fourth inch atrophy of thigh. The effusion disappeared under the use of thermo-cautery and compression. Wiring patella under ether, April 19, 1887, through a longitudinal incision; wire left in; rubber drains; bichloride dressing; no suppuration or fever; discharged in five weeks, wearing short posterior splint. At end of two and one-half years: weight, 215 pounds; circumference of thigh, one inch, of calf, one-half inch less than left; perfect power of extension; flexion to ninety degrees only; bony union; he says knee feels weak and he is afraid to run.

Case II.—McM——, male, aged fifty, fell through hatchway, striking on knee, May 10, 1882. Compound, comminuted fracture of left patella; loose fragments removed and remainder sutured with wire; death on eleventh day from septicæmia. Chambers Street Hospital. By Dr. W. S. Halstead, Acting Attending Surgeon.

Case III.—S——, female, aged twenty-one, with ununited fracture of left patella; result of fracture one year ago and subsequent refracture. No power of extension; flexion good, moderate atrophy of thigh. Wiring with iron wire under "Lister." October 23, 1878. Fragments only imperfectly coapted, a triangular interval left between them. Suppurative arthritis and abscesses in thigh. Death from exhaustion on January 6, 1879. Chambers Street Hospital.

THE TREATMENT OF TYPHOID FEVER; A REVIEW OF RECENT DISCUSSIONS.[1]

By SIMON BARUCH, M.D.,

ATTENDING PHYSICIAN TO MANHATTAN GENERAL HOSPITAL, NEW YORK JUVENILE ASYLUM, ETC.

The frequent revival of this subject in our medical societies is evidence not only of its incalculable importance, but also of the instability of our present therapeutic methods.

Brilliantly and learnedly though we may discuss typhoid fever, favorable though our individual statistics may be, still the figures of our Board of Health reports bid us "mend our ways" in language more eloquent than human tongue or pen can formulate. Twenty-five to forty per cent. is the death-rate from typhoid fever in our American cities; twenty-six per cent. is the mortality of the New York hospitals in recent years, according to Dr. Delafield's investigations. The import of these figures cannot be overestimated. May they be changed? Happily, there is a method of treatment which has the sanction of long usage, the authority of judicious clinical observers, and the evidence of unimpeachable statistics. To further the universal adoption of this method, I propose to devote all the energy of my nature, because I am a proselyte myself. I said, only a few years ago, from this platform: "Plunging a typhoid fever patient into a tub of cold water may suit a German soldier, but it is not adapted to our American constitutions." I have lived to regret these words of derision, and repenting thereof, I warn my colleagues against this very prevalent error.

In one of the recent discussions a hospital physician doubted the testimony of Vogl, Brand, Juergensen, and others, although they speak from several thousand cases, to the fact that the cold bath does not "produce the impaired circulation, cyanotic condition of lips and extremities, and bad pulse, which he had seen in cases in which even the cold pack and cold affusions produced these untoward symptoms." That this gentleman has the correct conception of the true rationale of the modern cold bath in typhoid fever is evident from his assertion that "the general nerve-depression was the main factor to be considered, and that it afforded the true explanation of the efficacy of the cold bath, when judiciously used." Despite this sound doctrine, he said, in the beginning of his remarks, that he was "personally opposed to the cold bath treatment." "In typhoid fever, however, with high temperature, it had seemed to him desirable to employ the cold pack or cold affusion, and he did not doubt that in some cases it was of real benefit." It would be difficult to reconcile these views, did we not find an explanation in the different methods referred to. The cold pack differs vastly in effect, and in its indications from cold affusions. The pack, if properly administered, is a mild antipyretic and soothing (sedative) procedure, while the affusion is, next to the douche, the most active stimulating procedure known to hydrotherapy. How these can be classed together, in their effect upon fever cases, is a problem I am unable to solve, and it becomes more difficult still to discuss the effect of these distinctly opposite measures as analogous in effect to the bath at 65° F., which differs entirely from both. The truth is that our conceptions on the subject of hydrotherapy are exceedingly vague. This is, perhaps, the chief cause of the absence of unanimity upon, if not of the antagonism to, its application in typhoid fever, in which its grandest triumphs have been achieved. This fact was clearly demonstrated again in one of the recent discussions at the Academy of Medicine. The author of the essay replied to the charge I felt called upon to make, that the cold bath is rarely applied methodically in this city, according to its most successful method (Ernst Brand's), that my "lament was not justified, so far as he was concerned, because he had resorted to the bath ever since Liebermeister first demonstrated its advantages." Now, it has been distinctly demonstrated that Liebermeister, although more successful than those who follow the expectant plan, has not attained the success in his treatment by baths which has crowned the efforts of Juergensen, Vogl, and others, because he has not followed the strict method of Brand, which is antifebrile, and not simply an antipyretic method. Liebermeister is the advocate of strict antipyresis, and he originated a plan of treatment quite distinct from that of Brand and his followers, a plan whose aim it is to produce by cold baths decided remissions in the fever, during which he administers large doses of quinine, with the view to maintain these remissions. His method gave a mortality-rate of 10.8 to 18.8 per cent. in the Munich Military Hospital, while the strict Brand method never exceeded 4.7 per cent., and averaged lately 2.7 per cent. in the same hospital.

Hence, if the gentleman referred to followed Liebermeister's method, it is not surprising that his results discouraged him.

During one of the discussions at the Academy of Medicine, on January 16th, I took occasion to refer to the vagueness of the term cold bath in this city, by citing, as examples, two cases occurring in two of our largest hospitals, under two of the gentlemen who had spoken disparagingly of the cold bath treatment. One of these, as related to me by the house physician, had the bath (?) administered by being wrapped in a sheet and sprinkled with ice-water until the temperature fell to a satisfactory point; the other was also wrapped in a sheet, which was kept saturated with ice-water by a sponge until the temperature was reduced from 106 to 101°. Surely these are not fair specimens of the cold bath treatment, and the fatal result in both cases cannot fairly be charged to this method. The experienced hydrotherapeutist never uses ice-water for a prolonged application. Water below 50° is sometimes used in the douche for ten to twenty seconds. But the aim of all hydrotherapeutic measures is to refresh, to stimulate the nerve-centres, never to induce a sedative effect. This must be clearly understood as the first principle of scientific hydrotherapy, and it is even well understood by the empirical hydropath to-day.

I submit, therefore, that until we adopt an approximately uniform cold bath treatment of typhoid fever, our discussions of this method will be nugatory, and our patients will continue to swell the mortality lists.

It has been objected to Brand's rule for bathing, that the intelligent physician should not be hampered by strict

[1] Read before the Section on Theory and Practice of Medicine, New York Academy of Medicine, February 18, 1890.

rules, that he should be allowed to use his judgment in each individual case. This is a valid objection. But have we not a rule, in other cases, which the profession have followed with advantage for many years? The successful treatment of a tertian intermittent (for instance) depends upon cinchonization of the patient before the paroxysm is due. Whether it is given in one dose, three hours before the paroxysm, or in several doses up to this time, is left to the judgment of the practitioner. But what success would accrue to the man who administered his large dose of quinine immediately after the cessation of the paroxysm? As a result, thirty six hours, or more, would elapse before the next paroxysm, during which interval the cinchonizing (protective) effect would cease. What success would another man obtain if he insisted upon using a tincture, decoction, or the powder of Peruvian bark instead of quinine for the treatment of a malarial remittent? Both would be classical methods (new and antiquated) of managing the malarial fevers; but they would be as flagrant violations of the recognized principles of this treatment, as is the resort to packs or spongings as substitutes for the Brand bath in typhoid fever. It does not follow, in the one case any more than in the other, that the physician must blindly follow the rules laid down. Quinine must be administered according to the condition of the patient and stage of the disease; but the rule to cinchonize the patient before the expected paroxysm is due, must never be lost sight of. The bath may be a little warmer, a little shorter, or longer, but the guiding principle, to keep the temperature three-hourly below 103° (merely as a test of its antifebrile action) must not be lost sight of. In the one case cinchonization protects the patient against the return of the attack, in the other the reduction of temperature indicates a condition of the nervous system which protects the patient against the deteriorating influences of the infective process. A slipshod, half-hearted method in the one case is as detrimental, if not so often fatal, as in the other. Another analogy may be drawn in the salicylic treatment of rheumatic fever. It has been well ascertained that pure salicylic acid or its compounds will control the pains and ameliorate the course of rheumatic fever. To accomplish this purpose, the physiological effect of the salicylates, tinnitus aurium, is in the majority of cases necessary. Twenty grains, repeated at definite intervals, usually suffice. The effect upon the distressing symptoms is as positive in relieving the pain, diminishing the fever, etc., as is the effect of the bath at 65°, in typhoid fever, in refreshing the system, brightening the patient, improving the appetite, reducing the temperature, etc. Doses of one to two grains of salicylic acid administered hourly, or five grains administered every two hours, would accomplish about as much as sponging or a wet pack will do in typhoid fever; these small doses will, after accumulating in the system, afford some relief; the sponging and pack will afford some comfort. But if the effect is to be decided and beneficial the rule must be adhered to, to obtain the physiological effect of the remedies in both cases, although we may deviate in minor points from it. It would be as absurd to insist upon the strict three-hourly bath of 65° in the third week of a feeble typhoid case, as it would be to insist upon twenty-five grains of salicylic acid in an advanced rheumatic case, whose heart is feeble, or who has gastro-intestinal disturbances. Entire abstinence from or a modification of the treatment is indicated in both cases. The therapeutic principle remains the same.

Brand's rule, however, is not inflexible, as the following extract from a letter received on Saturday, February 15th, from Dr. Brand illustrates. Referring to a case where bath treatment was detailed in one of our journals, he says: "By following my rule is not to be understood such treatment as was given by Dr. —— to the child, which was so far reduced in strength and nerve-power that it should not have been put into a cold bath, but into a warm one, until it gradually became accustomed to the cold bath, for twenty-four hours. To me it is surprising that Dr. —— did not obtain greater disadvantage from the low temperature used in this case; it was a special piece of good luck. I always use warmer baths for twenty-four hours, usually temperature of the room, if the patient has been ill over four days; often, also, from the beginning." From this extract it will be gathered that Brand does not advise the plunging of every case into a bath of 65° F. without regard to individual condition. The truth is, that in no method of treatment is good judgment more necessary than in the management of typhoid fever by the cold bath.

As has been well said by Dr. Kinnicutt, in summing up the discussion before the Practitioners' Society, "In the United States opinions upon the result of Brand's method of treatment could only be formed through statistics, which, except in a few isolated cases, had not even been attempted. We were, however, very familiar with the expectant plan of treatment, and the mortality-rate of typhoid fever so treated was very high. A study of Brand's statistics should lead to an effort, on the part of hospital physicians, to give a thorough trial to a method of treatment which had been followed, apparently, by brilliant results." This wise suggestion must be applauded.

But how is this method to be tested, if, as is evident in the recent discussions, there is no uniform method of treatment; when gentlemen class cold sponging, the wet pack, the ice-sprinkled sheet, the graduated bath of all temperatures, from 70° to 90° F., as the cold bath treatment? It is remarkable that American physicians, who are usually so practical and ready to utilize the most successful methods, have so long stood aloof from this well-proven treatment. This is due, it would seem from recent and previous publications, to a desire to adopt some modification of a seeming harsh measure. We are not accustomed to discipline our patients, and yield too readily to their prejudices against cold water. Brand said, in a recent letter to me: "Only then may we expect a definite introduction of the method in America, when your medical men will decide to study the question thoroughly. Whoever is afraid of the cold bath (and everybody seems to be, the professors at their head!), whoever fears taking cold from it, whoever does not understand the action of the bath upon the healthy and diseased organism, should not treat typhoid with water."

The opinion expressed in the recent discussion, that "it is the greatest possible mistake to bring these data from Germany and apply them to the United States," is singular, since we do not make such distinction with regard to other therapeutic agents. On the contrary, the statistics furnished by Juergensen and Vogl, for instance, are the best possible guide for this or any other country, because they are obtained from hospital practice, civil and military, and they represent the comparative merits of various methods. Vogl is the chef of the Garrison Hospital at Munich. He offers us the records of eight thousand three hundred and twenty-five cases of typhoid fever treated there during forty-seven years. (Military records in Germany are proverbially accurate.) Vogl mentions each year the type of the disease, derived from symptoms and autopsies, the treatment pursued, and the results. The mortality ranges from 40.3 per cent. (1843) to 23 per cent. (1877 and 1878). Since 1875, when the cold bath treatment was systematically begun, the mortality per cent. has never exceeded 4.7 per cent., and the average was 2.7 per cent.

May we trust these statistics, or not? A brief examination will decide this point for any fair-minded person. We will take, at random, the following extracts as an illustration of how this report is made:

1841: 180 cases, 57 deaths, 31.7 per cent. mortality.

Remarks.—Frequent complications, gangrene of toes and eyelids.

Treatment.—Absolute diet, aqua chlor. internally.

1842: 165 cases, 64 deaths, 38.8 per cent. mortality.

Remarks.—Granular matter, size of pea to hazelnut found in spleen and mesenteric glands.

Treatment.—Evacuation according to nature's pointing, mildly antiphlogistic, sinapisms, vesicants, cold fomentations. In plethoric subjects, general or local bleeding; in the last quarter small doses of calomel, in single case venesection.

1850: 181 cases, 24 deaths, 13.3 per cent. mortality.

Remarks.—Nurses frequently attacked, strict attention to diet, light covering, ventilation, frequent change of bed, occasionally cold compresses and packs. Disinfection of surroundings and evacuations. Prepared charcoal the most effective remedy for diarrhœa. Inhalation of sulphuric ether for laryngeal ulcers.

1851: 222 cases, 45 deaths, 20.3 per cent. mortality.

Treatment.—Calomel, cold compresses and affusions (2d trimester). Emetics and expectant, entire wet pack twice to three times daily. Vinegar baths. Aqua chlor. internally.

1859: 351 cases, 55 deaths, 15.1 per cent. mortality.

Remarks. Treatment.—Two to three times daily cold douche on head and neck in warm bath. Complication, ulcers of cornea.

1866: 327 cases, 52 deaths, 15.9 per cent. mortality.

Remarks.—Epidemic in Maximilian II. barracks; three nurses sick; very severe cases; numerous roseola spots, ecchymoses, petechiæ, bedsores, otitis, diphtheritis, etc.

Treatment.—Cold water wrappings, bathings, and packs without special result. Diphtheritic complications treated successfully by hot vapor.

1872: 425 cases, 62 deaths, 14.6 per cent. mortality.

Remarks.—There was a severe epidemic in the city also; 12 nurses, of whom 4 died, affected; 27 house-infections, with 5 deaths.

Treatment.—Constant ventilation, change of bed; baths of 17° when temperature reached 39° C. and over, every two or three hours. Each patient averaged 36 baths. Ice-water washings.

1874–75: 141 cases, 31 deaths, 32 per cent. mortality.

Remarks.—Severe complications, great heart feebleness; bloody stools; twice pulmonary hypostasis, larynx affections; cholera twice.

Treatment.—Baths of 18° R.; thirty-two to each case; stimulants.

Since 1875 two methods of treatment were pursued at two different stations of the garrison. In Station I. the combined method, consisting of baths of temperature of the room, with quinine three to four grammes daily, salicylate of soda; and in Station II. the methodical bath of Brand, consisting of a bath from 60° to 65° F., for fifteen minutes, whenever temperature reached 103° F. No medicine, freely ventilated barracks.

Results.

Combined Treatment.

Number of cases	667
Mortality	7.6 per cent.
Average stay in hospital	40.7 days.
Average duration of fever	1.9 week.
Percentage of complications	102
Average number of diarrhœas per day and person	1.9

Strict Bath Treatment.

Number of cases	221
Mortality	2.7 per cent.
Average stay in hospital	47.3 days.
Average duration of fever	1.8 week.
Percentage of complications	65.2
Average number of diarrhœas per day and person	0.7

This report continues by fully enlarging upon the nature of each complication, and with a minute, practical, and judicious analysis of the bearing of the treatment upon every essential symptom. Special stress is laid upon the necessity of thoroughly ventilated and cold barracks, and ample nutrition. This report must be read in full in order to appreciate it. It may be said, without fear of contradiction, that no therapeutic question has been so thoroughly canvassed as has been done in this report. Can anyone familiar with its source deny credence to its statements or gainsay its deductions? It affords testimony that is unimpeachable to the effect upon the same type of patients (soldiers of about the same average age and condition of health) under the depleting, nihilistic, expectant, and water treatment, and also striking evidence on the difference between a combined water and medicinal (antipyretic) method and the systematic Brand (antifebrile) method. The numbers are sufficiently large to entitle them to respect, and the periods are sufficiently long to exclude possible errors due to more or less virulence of types in the disease. It demonstrates the interesting point that the combined method at times reached quite as high mortality percentage as in many of the years preceding, when the expectant treatment was employed; but that the systematic, unremitting bath treatment (Brand's method) never exceeded in seven years 4.7 per cent., and averaged 2.7 per cent., neither one of which figures had ever been reached before (the lowest was 9.9 per cent. in 1865, under quinine and camphor treatment; the next, in 1869, 11.5 per cent.).

That the baths must be systematically used according to the rules laid down by Brand, in order to insure success, is clearly demonstrated by the report of 1875 to 1876. Although the treatment was by baths averaging thirty-two to each patient, the temperature of the bath was 72.5° F., only 6½ degrees below the temperature required by the Brand method. The mortality was thirty-two per cent.; severe complications were not prevented. This experience inculcates the lesson we have so often learned in this country, that a half-hearted execution of the Brand method is not as useful as the expectant symptomatic treatment.

If scepticism ventures to cast a doubt upon the testimony of Vogl's copy from the military reports, this doubt will be shaken by confirmatory evidence from other and independent sources. In the Poliklinik at Tübingen Juergensen had observed even better results. During nine years 217 cases were treated by strict bathing, according to Brand. Only one of these died. Juergensen claims "a powerfully stimulant influence upon the central and reflex organs; he uses cold compresses for diarrhœa, and continues to bathe even when there is intestinal hemorrhage."[1] Into this clinic, we are informed, most cases are brought early, because the neighboring country people have great faith in Dr. Juergensen. Is it fair to doubt his statistics, furnished by Betz, his chief of staff?

If there exists any doubt, further proof may be obtained from the official army reports of the second German army corps, whose mortality was reduced from 26.3 per cent. to 4.3 per cent. by systematic bathing. The latter was so conspicuously successful that an order advising its general adoption in the army was issued by the surgeon-general. These statistics have been regarded with suspicion in one of our recent discussions. But if we reflect that these military data have long been open to inspection, and have never been doubted by the numerous antagonists who have in Germany broken lances against the Brand method, all objection must be silent. That these reports confirm the statements of Brand, the originator of the method, is important, because this gentleman has been unjustly charged with partisanship for his own creation. He had pursued the practice for thirty years, almost entirely in a private clientèle, with the result of one death in three hundred and forty two cases. But it must be remembered that this marvellous success was due to the strictest attention to detail, and the subjection of every case to the bath treatment that showed the slightest suspicion of typhoid symptoms. It is only by this course that cases may be brought under the influence of the cold

[1] In this connection, a case mentioned by Dr. Peabody in the recent discussion is of interest. A patient, for whom cessation of the baths had been ordered on account of intestinal hemorrhages, watched for the absence of the nurse and plunged into the bath which stood near his bedside. The result was a cessation of the hemorrhage. When I saw him, by courtesy of Dr. Peabody, several days later, he was bright, and was engaged in a plea for rice-pudding.

bath before the fifth day, a point which is emphasized as essential for reaching the phenomenal success attained in the twelve hundred cases reported by Juergensen, Vogl, Brand, and in the second army corps. Need we abandon the treatment altogether because "it is difficult" (as was said in one of the discussions) "to make the diagnosis before the fifth day?" This is simply a valuable rule; the more nearly we approach it the more complete will be success, as Vogl has plainly shown. But I desire to emphasize the fact that it is not at all difficult to place typhoid cases under the cold bath treatment before the diagnosis is clearly made. Every suspicious case of fever should be placed in the bath, if the temperature reaches 103° F. This is the course pursued at Munich and Stralsund. That no harm can result from it may be easily demonstrated. I pursue it constantly in private and hospital practice. The following case will illustrate:

On November 10, 1889, the police sent an ambulance call to the Manhattan General Hospital, for a case of Paris-green poisoning which had been found on the street. The stomach, on being washed out, was found to contain no poison. Patient's temperature was 106° F., pulse 140, tongue brown and dry; he was apathetic, and could give no account of himself. He had no cough; his respiration was not out of proportion to the pulse. Pressure in the right iliac region made him shrink. A graduated bath, 90° F. to 68° F., reduced his temperature to 101° F. in three hours; another bath, when it rose to 103° F., reduced it to 100° F. It never rose to the bath rule figure (103° F.). On the second day consolidation was made out in the upper posterior half of the right lung. The patient was convalescent in five days. He was bathed on suspicion with benefit.

If this rule is adhered to in all suspicious cases, many would come under treatment before the fifth day, and almost surely be saved. If the case be one of simple fever of an ephemeral type, no harm will ensue, especially if the graduated bath be used, until the diagnosis is clear.

A mild bath treatment is advantageous in any febrile attack in which the temperature reaches 103° F.; if it prove to be typhoid, valuable time has been gained; if its course is rapidly terminated, nothing is lost, except the satisfaction (?) of plying the patient with aconite or antipyretics. In private practice this may be done wherever a bath-tub can be obtained; in hospital practice it may be done by ordering the house-staff to put every case of fever not clearly diagnosable, and having a temperature of 103° F., into the graduated (Ziemssen) bath, from 90° F. down to 68° F., or less, for half an hour, with gentle friction during the whole time. The gradual lowering of each bath accustoms the patient and his friends to overcome their prejudices.

Brand's method has been most thoroughly canvassed in Germany. It is far from universally adopted. Before the discovery of our active antipyretics, and when high temperatures were the chief points of attack, the cold bath treatment enjoyed more universal acceptance than it does to-day. That the sway of antipyretics is now passing away, even in this country, is evident from the recent discussions. The lethal influence of high temperatures is happily losing its hold upon the profession. But let us take care that the receding tide do not only sweep away the antipyretic rubbish which has accumulated during the past fifteen years, but also the cold bath treatment, which had unfortunately been classed among antipyretic measures. Whenever we give up this fallacious idea, the cold bath treatment will replace the unsuccessful antipyretic treatment completely. In the Fourth Congress of Internal Medicine (1885), eminent clinicians expressed almost unanimously the opinion that, "until we obtain a specific curative agent for typhoid fever, such therapeusis is to be preferred which is capable of diminishing or removing the effects of the morbific agents, and that this aim is most surely fulfilled by hydrotherapy; that medicinal antipyretics act only against temperature elevation, but do not, like the bath, produce a modifying effect upon the fever process." Fiehlene, Liebermeister, Jacksch, Struempell, Rossbach, Stintzig, Bauer, Heubner, Juergensen, Zuntz, Bamberger, were among these speakers. Since that discussion brought out the true mission of the cold bath, as first enunciated by Brand, a reaction is taking place in its favor. But this reaction is just reaching our shores. I passed through a similar experience in another discussion. When I opened the crusade, in December, 1883, against vaginal injections after normal labor, this antiseptic prophylaxis was being rapidly abandoned in Germany; but some of our foremost obstetrical teachers were warmly espousing it, and I had the satisfaction, by constant agitation, in which statistics with the deadly parallel[1] played an important rôle, to be instrumental in hastening the abolition of this useless and injurious practice.

The present effort to win the American medical profession over to a treatment of typhoid fever whose triumphant results are undoubted, will, I am convinced, be crowned by the same success, because the clinical proofs are equally abundant and unimpeachable. As in agriculture, the frequent turning of the soil renders the latter fertile and aids the growth of seed planted in it, so does a healthy scepticism, which stirs and upheaves the mind, furnish a most fertile soil for the growth of an idea. Thus it has come to pass that the cold bath treatment is winning golden opinions, even from those who were reluctant and halting in its acceptance.

Goldtdammer[2] says: "In 1868 the picture changed completely, although the same hygienic conditions existed; the treatment was changed on the 1st of January, 1868, the cold bath being adopted. With the latter a revolution occurred, which even the nurses noticed, reducing the mortality to five per cent."

Bahrdt says that the mortality of typhoid fever in the Jacobs Hospital at Leipsic, was reduced by the bath treatment from 18.2 per cent. to 9 per cent. Riegel reports a reduction in Bamberger's clinic from 20 per cent. to 4.4 per cent., by baths. Schultz, in Bremen, reduced the mortality to 2.7 per cent. by strict bathing.

Guttstadt, who is the censor of the Statistical Bureau in Berlin, said in a lecture before the Verein für innere Medizin in Berlin, in 1887, that "an important factor in the diminution of mortality is the more successful treatment now used, especially Brand's method."

Besides the well-known clinicians above mentioned, Ziemmssen, Immerman, Bartels, Riegel, Leichtenstern, Nothnagel, Fiedler, Mader, Trier, Muni, Ebstein, Weil, Boehm, Bettelheim, Pfuehl, Senator, and in France, Tripier, Bouveret, Glenard, Teissier, and others, may be cited as advocates of a more or less strict bath treatment of typhoid fever.

There are still many good clinicians opposed to its adoption. But the well-informed observer will agree that it is at least safe to follow the lead of the teachers and clinicians mentioned. In the recent discussions much was said by some of the speakers on the subject of intestinal antisepsis in typhoid fever, and the suggestion was made, with some show of practical value, of sterilizing as far as possible the intestinal tract, either by internal antiseptics, as naphthol, or by high irrigation. Fortunately, the attentive reader of the MEDICAL RECORD of January 18, 1890, which contains this discussion, finds on page 67 a note on the influence of drugs on putrefactive processes in the intestine, as shown by the experiments of Stieff in Gerhardt's clinic. Stieff obtained negative results, camphor being the only drug which appeared to possess a slight restraining power on putrefaction. The attempt to free the intestinal canal in typhoid fever from putrefactive agents would, therefore, seem to be Quixotic. Putrefaction is due to the presence of decomposing tissue elements and secretions from intestinal ulcerations. Prevent the latter, or limit them, and we remove the cause. That this may be done can no longer be doubted, if we may

[1] New York Medical Journal, March 22, 1884.
[2] Arch. f. Klin. Med., 1887. Vogl's paper.

credit Vogl's testimony to the great diminution of diarrhœa and meteorism by the bath treatment. The cold bath, which reduces the temperature, strengthens the heart, deepens the respiration, improves the digestion, increases diuresis and perspiration, brightens and refreshes the patient, and must prevent the tendency to accumulation of effete material in the system.

Another point brought out by one of the speakers in the recent discussions is the value of solid food in the third week of typhoid fever. It is not a simple coincidence that the advocate of this method of feeding is also the only advocate of systematic bathing who appears in this discussion. Tripier and Bouveret dwell upon the remarkable appetite and digestive power of patients who are systematically bathed. Dr. Austin Flint, who introduced systematic bathing into his ward last spring, tells me that the appetite of his patients is difficult to appease. How different the condition of the stomach is under the expectant or antipyretic treatment, every experienced physician knows but too well. As Brand graphically says: "While under the water treatment, the tongue is moist, pale, without fur, the pharynx free from pain, the stomach and intestines free from catarrh, the latter only showing swollen glands; we find under other treatment the tongue hard, brown, and dry, saliva is absent, swallowing is painful, stomach and bowels utterly incapable of digesting, their mucous lining covered with ulcers, the bowels distended; and in this condition the School demands —that the patient be well nourished. What a singular demand!" The digestive organs are in so nearly a normal state (under bath treatment) that I often asked myself the question if it may not be safe to give more solid food, in order to appease the hunger. I find in *Virchow's Archiv*, 89, S. 95 and 303, an essay by Hoesslin, who proves that even in fever and diarrhœa, so long as these do not reach a very high temperature, as is usual in typhoid fever, the nutriment is almost completely taken up; that there is, therefore, no reason to give fever patients less food because it is not digested and absorbed. He regards it necessary to offer typhoid patients the largest possible quantity of concentrated food, as milk, meat, eggs, flour preparations, etc., all, however, in minced and liquefied form.

Tripier and Bouveret give milk, bouillon, extract of beef, coffee and tea with milk, one-quarter of a litre always after the bath; hence eight times daily. During the time of "relative apyrexia" they allow rolls, rice-cream, tapioca, chocolate, soft eggs, four daily, meat-juice, etc. So soon as temperature is normal, they allow roast chicken, bread and milk, lean meat, rice, baked brains, white lean meat, a little boiled beef, ground fine, etc. Vogl gives from the first day, coffee, meat broth with a little flour and egg, milk, one bottle of red wine daily, later bouillon, eggs, so that the patients receive daily 50 grammes albumin, 45 grammes of fat, and 200 grammes carbohydrates, "a food quantum that could not be permitted to patients who are not bathed." Brand says the most important element of nutrition, besides the food, is a good stomach. "Where this is lacking, all foods are useless. As we may obtain it by the systematic bath treatment, the latter is demanded."

The most important question in this review of the recent discussions is: What constitutes the cold bath treatment?

The statistics referred to, showing a reduction of mortality to less than three per cent., and in 1,200 cases treated before the fifth day to less than one per cent., were not obtained from cold sponging, wet packs, cold coils, cold affusions, graduated baths, or any other agreeable substitute. They were the result of methodical bathing according to Brand's original method. As there seems to be much vagueness of conception on this point, I deem it important to furnish an outline of the method, as I have learned it from the study of Brand, Vogl, Tripier, and Bouveret, and correspondence with Brand himself.

1. The first principle is to bathe early; even before diagnosis is clear. No harm is done at least by a graduated bath, viz., reduced from 90 to 68° F. for a quarter or half an hour. This is the only modification of the method which is advisable. It accustoms the patient to the treatment and gains time. It should be resorted to as soon as the temperature in the rectum reaches 103° F. I am in the habit of bathing the patient's face and chest with ice-water before placing him into any bath.

2. As soon as the case becomes defined or even suspicious, the strict bath, 65° F., should be used. The tub must stand at the patient's bedside, filled two-thirds with water at 65°. The patient receives a stimulant, and has his face and chest washed with ice-water. He is undressed and gently lifted into the water. A gasp or shudder follows, perhaps an ejaculation of distress. But gentle reassurance by word and deed, a calm demeanor devoid of haste, and avoidance of force, will do much to quiet the patient. With one hand under his head, if necessary, the other is used to gently practise friction over the submerged parts. Another nurse pursues the same course, if possible. This important feature of the Brand method is, I have observed, frequently neglected, and to its neglect may be charged the occurrence of collapse, cyanosis, and chill. Gentle friction with the outstretched hand produces a rosy hue of the skin; the superficial vessels are dilated. By thus exposing a large supply of blood, the cooling is more rapid. The bath should be continued in this manner for fifteen minutes, no matter how urgently the patient desires to be removed. A pinched countenance, chattering of teeth, unless excessive, or a small pulse, must not be taken as indications for removal. If the face becomes cyanotic or the respiration embarrassed, the bath must cease. Every five minutes during the bath, water at about 60° F. should be gently poured from a pitcher over the head of the patient, after a folded handkerchief has been tied like a bandage with the knot over the nucha. This prevents the water from running over the face, and spreads it over the head.

Before the patient is removed from the bath, a linen sheet should be spread over a blanket to receive him. If his temperature has been high, this sheet alone is wrapped around him, while his lower extremities are also covered with the blanket. If his temperature has not been over 103.5°, the whole body may be wrapped in the blanket over the sheet and hot bottles placed to the feet. He is then left to dry for ten or fifteen minutes; something hot is now given him; his night-gown is replaced and his temperature is taken. A piece of old linen sheeting (cotton should never be used for any purpose in this treatment) is now folded into a compress of four folds, gently wrung out of water at 60° F., and placed upon the entire anterior portion of the body, from the neck to the pubis. It is renewed every half-hour if patient is not sleeping. This process is repeated every three hours, so long as the temperature reaches 103°, night and day, unless the patient is asleep naturally. Stupor, coma, or delirium are always indications for the bath, even if the temperature be below 103°. In these cases, placing the patient semi-recumbent into a half-bath at 95° and pouring several basinfuls of water at 60° over his head and shoulders, is a more valuable procedure than the cold bath. Let it be distinctly understood that the Brand bath is not "a nervous sedative" (as has been claimed for the cold bath in a recent paper before our State Society); but a refreshing measure, a stimulant, if you will, by which the depressing effects of the typhoid poison are to be counteracted. The nervous system is tottering under the toxic influence arising from the infective process; all the functions are so enfeebled thereby, that the processes of life are barely maintained. The impact of cold water upon the large peripheral surfaces deepens the inspiration; more oxygen is inhaled, more CO_2 given off; the cooled blood rushes to the nervous centres, vivifies and refreshes them; the heart and stomach respond, the secretions become more active. All this is evident to the most superficial observer. Hence the cold bath fulfils com-

pletely the indication referred to in the recent valuable paper of Dr. Loomis before the State Society. He said, "In the light of recent experiments we are forced to the position that, in the treatment of all acute infectious diseases our successes would be in the judicious measures which Dr. Chambers has long ago designated as restorative." The rationale of the restorative action of the bath is so simple, that if once appreciated, no attempt will be essayed to substitute it. The gentle friction stimulates the coats of the superficial vessels, whose muscular coats, as Marey and others have shown, are paralyzed by the infective process (giving rise later to heart failure from absence of propulsive aid). These vessels are thus dilated, as is evident from the ruddy hue of the skin; the obstacle to heat dissipation is removed also (Weyrich has demonstrated that gentle friction increases heat dissipation sixty per cent); the occasional cold douche over the head and shoulders again contracts the vessels briefly. Thus their activity is maintained. How different the effect must be of laying the patient into the cold water and leaving him in it undisturbed for fifteen minutes, or wrapping him in a sheet and sprinkling ice-water over him, very little reflection will indicate. Winternitz has demonstrated by sphygmographic tracing this restoration of tone to the vessels by the bath and friction; and the most superficial observer will note the increase in the force and decrease of the frequency of the pulse after it. It is therefore a true "restorative."

Let me give you the testimony of one of the clearest-headed teachers of therapeutics in Germany, F. A. Hoffman, of Leipzig, whose recent work "Vorlesungen über Allgemeine Therapie," 1888, has received the highest encomiums from Ewald and other reviewers. "A most decided advantage of the cold bath (p. 438), upon which I lay the greatest weight, is its effect upon the nervous system. I have already referred to its excellent action in every respect. It remains for me only to remind you how favorable the tonic influence must be just in such cases in which an elevated temperature has produced paralysis, and from this point a retro-action must result favorably to all organs of the body, as is sufficiently well known to us practical men. Thus we see the patient torn from his somnolence, we see him eat and drink, we see the innervation of the heart, of the bronchi, of all the vessels maintained in force, so that bedsores, hypostases, and thrombosis become rare. Respiration is deepened and slowed, heart action calmed, the pulse is usually reduced ten to fifteen beats. Blood pressure is raised; hence the heart is strengthened. Heart feebleness also forms for us an indication for the cold baths, but two groups must be distinguished, viz., that in which the skin is very hot, from that in which it is cool. The weaker the heart, the more does the energy of the peripheral circulation sink; a further cooling can only act reflexly; hence, only very short and cold affusions are indicated, or wine and camphor. But where there is great surface heat with a miserable pulse, prolonged cool, not too cold, baths are indicated. In these cases the usual stimulants have not served me so well. The improvement of the circulation of the glandular apparatus by the cold baths must be noticed. I cannot doubt the favorable effect of cold water upon the general nutrition; many experiences on healthy and fever patients give me this assurance. Cold water is a nerve-stimulant, which possesses the least shadowy sides of stimulants. With a little care unfavorable reaction may be avoided, and we have only the invigorating effect already referred to, which must redound to special advantage in fevers. Anæmia of the inner organs is removed when the blood is driven from the skin by the cold baths; and thus the function of the heart, brain, and large glands is at least temporarily aided."

The cold bath is not intended as a specific curative measure; its action is analogous to that of peripheral stimuli applied to other toxic conditions.

The stupor due to opium toxæmia furnishes a fair analogy. Here we have a poison circulating in the blood, which requires time for its removal. In mild cases the system may eliminate it without assistance, but generally very active stimulation by the faradic current, cold douches, incitement to walk, etc., are required to prevent the patient being overpowered by the stupor. The latter is the chief manifestation, the pulse and respiration furnishing others. Now, if we resort to treatment so soon as we find the respiration slowing up, we may prevent the stupor; if we wait longer it will become difficult, if it do not become impossible. The treatment is continued until the respiration and pulse indicate that the poison is no longer circulating in the blood. Almost the same object is in view in the treatment of typhoid fever by the cold bath. The elevated temperature (103° F.) is regarded as the guiding manifestation in this case, as the retarded respiration is in the other. We no more try to cure the former by the bath than the latter by faradization. If we can diminish the force of the toxic effect arising from the infective process in typhoid fever, before it accumulates and overwhelms the system, we accomplish the same result that we reach in opium poisoning by early faradization and other measures, viz., we endow the system with nerve-stimulus or force to tide over the danger of toxæmia, until the offending elements are eliminated. Our antitoxic measures will prove efficient in proportion to the earliness, persistency, and good judgment with which we apply them, in the one case just as they will in the other. For the object is almost analogous in both cases, although the conditions are not. What would be thought of the application of a mustard-plaster or the smelling of hartshorn for the production of a peripheral stimulus to arouse a case of opium narcosis, which barely responds to flagellation or a strong faradic current? Sponging the body in typhoid fever bears the same relation to the cold bath; the only difference being that in the one case the feebleness of the stimulus is at once apparent, while in the other days and weeks may pass ere we discover its inadequacy, and then it is too late, as experience has shown. Dr. Peabody has told us how persistently he has tried sponging in several hospitals, and how ineffective it has proven. The bath at 65°, when accompanied by frictions, will prove not only a valuable antitoxic agent, but a true restorative to the failing powers.

Regarded in this light, and not in the light of a heat-reducing measure, this mode of bathing (not sponging, wet-packing, or ice-coil) must save many lives that are now daily sacrificed.

47 East Sixtieth Street.

ACUTE ASCENDING PARALYSIS, FOLLOWED BY ATAXIC PARAPLEGIA.[1]

By SANGER BROWN, M.D.,

Professor of Mental and Nervous Diseases, Post-Graduate Medical School, Chicago, Ill.

Acute ascending paralysis was first recognized and described by Landry in 1859. Since that time numerous supposed cases have been reported, though the points of similarity between some of the symptoms of the disease and acute ascending myelitis renders it somewhat doubtful under which heading some of the cases most properly belong.

The etiology is obscure, but remote influences correspond pretty nearly to those found in acute myelitis. The disease is more frequent in males than females, and chiefly occurs between the ages of twenty and forty. As an exciting cause, exposure to cold ranks first. Convalescence from small-pox, typhoid fever, and diphtheria have also been mentioned in this relation. Some authors regard syphilis as a frequent cause, but this opinion has not been generally received. No constant premonitory symptoms have been observed. General malaise, slight fever, pains in the head and back, formication, numbness in the feet and finger-tips have all occasionally preceded the onset. The first definite symptom is usually weak-

[1] Read before the Chicago Medical Society, March 3, 1890.

ness, beginning in the feet, and extending steadily up the legs. It may begin somewhat earlier in one foot than in the other.

The paralysis appears first in the muscles that move the feet, then those which move the leg, and, later, in those which move the thigh. It then extends to the muscles of the pelvis, loins, abdomen, and thorax, in the order named. The arms are next invaded, either from below upward or from above downward. The diaphragm and the neck muscles next suffer, difficulty of swallowing comes on, and articulation becomes imperfect, or impossible. Unless the disease is arrested the patient soon dies from asphyxia, due to paralysis of the muscles of respiration. The sphincters may escape entirely, or suffer considerably. The sensory symptoms vary from slight subjective numbness and tingling, to a considerable degree of anæsthesia. Sensibility to touch is frequently blunted, and that to pain and temperature changes may be delayed. Pain is nearly always absent, and never prominent. At first the cutaneous reflexes and myotalic irritability are lost; but in most cases which do not terminate fatally it returns and may become excessive.

Although the muscles soon become flaccid they do not atrophy, nor present altered electrical reactions; nor is there any tendency to bed-sores—striking points of difference when the disease is contrasted with acute poliomyelitis. The cerebral functions are not involved. As a rule, there is no elevation of temperature. Enlargement of the spleen has been observed in several cases. Though from two to four days is the period usually occupied by the disease from its commencement till it ceases to progress, either from the supervention of death or otherwise, it may progress to a fatal termination in a few hours, or occupy so long a time as four weeks.

Though the order of invasion already described is most usual, considerable variation from it has been noticed. The arms have sometimes been involved before the legs, and bulbar symptoms have been said, in some cases, to take the precedence. Very rarely there has been diplopia, paralysis of accommodation, dilatation of one pupil, and in one case there was double facial palsy. After having advanced rapidly to a certain point the disease may stop, the muscles last affected being the first to recover. Though the whole nervous system, including the sympathetic and the muscles, have been examined by the most competent pathologists, only negative results have been obtained.

The traces of inflammatory changes in the gray matter, which a few writers claim to have found, have led them to pronounce the disease a form of acute atrophic paralysis. But the absence of fever, muscular wasting, and changes in electro-excitability are strongly opposed to this view. The occasional enlargement of the spleen has led to the hypothesis of a toxic influence, mainly acting upon that lower portion of the upper segment where its ramifications unite with the various cellular elements in the gray matter of the cord.

Now, so able an observer as Dr. Gowers makes disease of these filaments a working hypothesis by which the symptoms in this disorder and in ataxic paraplegia may be explained, and this case, so far as I am aware the only one of the kind on record, would seem most peculiarly to confirm Dr. Gowers's hypothesis.

In reaching a diagnosis the rapidly ascending palsy, with relaxation of muscles and loss of reflex action, without fever, pain, and loss of sensation, and if the patient survives without wasting of muscles or changes in electrical excitability, are the main points to be borne in mind.

General ascending myelitis is the only disease which may present considerable similarity in the mode of onset and early symptoms. But in this latter affection there is always much disturbance of sensation, there is a strong tendency to bed-sores and other evidence of trophic disorder; the muscles waste and will not respond to the faradic current, if the patient survives. A large majority of cases are fatal, and the prognosis is always grave until the march of the symptoms is arrested. Relapses are infrequent. As during the early stages the disease cannot be distinguished with certainty from acute myelitis, the treatment should be that most suitable for this latter disorder. Rest, lateral decubitus, and counter-irritation the whole length of the spine, are appropriate measures. Ergotin and salicylate of soda have each been employed with some apparent benefit.

History.—Following is a history of the case which furnished the text for this paper:

R——, aged forty-two, married, native of Ohio, was brought up on a farm, and has been by turns farmer, carpenter and builder, and merchant. Temperate, active habits, and disposed to work long hours. Family history good. Mother still living, aged seventy, and he thinks has cancer of the breast. At the age of sixteen had a severe attack of pneumonia, and ten years ago a severe attack of typhoid fever; in the meantime having had, while camping in the West, several severe attacks of malaria during which he was delirious when the fever was at its height. In the fall of 1883, forty days after exposure, had a small hard sore on the penis, which his physician pronounced syphilitic. No secondary symptoms were ever observed. About six months prior to June, 1887, began to suffer with occipital headache, which never left him; and often manifested violent exacerbations, which increased in frequency and severity until toward the latter part of the period, when diplopia sometimes occurred at the climax of an exacerbation. The character of the pain, he says, was steady, dull, and heavy. He ate and slept fairly, and was able to attend to business as usual. Tried many physicians and took various and numerous remedies, but without any relief.

On the morning of June 9, 1887, travelled by train about twenty-five miles to consult a physician in regard to his headache, and while sitting in the physician's office about sundown of that day, noticed a slight but distinct numbness of the toes of the left foot, as if the parts were "asleep." About two hours later, when he retired, the numbness had reached the ankle, but he noticed no weakness when walking. He awoke about 1 A.M., and thinking it might be time for an early train, which he wished to take in order to return home, he observed on going downstairs that the numbness had extended above the knee, and that the muscles of the leg were quite weak, so that he walked with difficulty. And at the same time he noticed that numbness had extended to the ankle on the other side.

When he rose the next morning at five, the numbness had extended to the hip on the left side and nearly to the knee on the right, and the weakness had increased considerably in both legs, so that it was only with great difficulty that he could walk to the railway station, a distance of about half a mile. When there he took a sandwich and cup of coffee for breakfast, but soon vomited, though he is certain that he had no fever at any time during the attack. He reached home at about 10 A.M. and found, upon trying to walk a few yards to his house, that the weakness had increased very considerably, so that he needed assistance.

Continued to grow weak throughout the day; the numbness and weakness of the right leg having overtaken that of the left, progressed evenly above the hips, but more slowly than it had advanced up the legs. He slept some during the night, and next morning, by holding on to the fence along the walk for support, reached his place of business, but returned almost immediately, the paralysis having progressed very markedly in degree. About 10 A.M., the numbness having reached the umbilicus, severe nauseous vomiting and hiccoughing set in and lasted pretty steadily for forty-eight hours. When the numbness had reached the umbilicus, it appeared in the finger-tips of each hand and extended nearly the whole length of the distal phalanges of the second and third fingers, and only at the extreme ends of the other fingers and thumbs. Here it ceased, and no weakness of the hands or upper extremities ensued, but the altered subjective sensation and blunting of tactile sensibility still remains as it does elsewhere.

The paralysis of the legs and lower trunk muscles appears to have been almost complete by the end of the first forty-eight to sixty hours; and it seems safe to say that extension ceased at the end of forty-eight hours from the commencement of the attack.

The patient is a man of active intelligence, and, after the disease had fully developed, often tried to discover any possible power of motion in the lower extremities, and was only able to make very slight pressure against the bedclothes with the outer side of each foot.

The sphincters were distinctly affected, but not greatly. Haste had to be made when he felt the desire to urinate or defecate—if the passage was loose—in order to prevent an accident. Constipation resulted probably from lack of exercise and paralysis of abdominal muscles.

The mind was clear, so that the patient kept the run of his business as perfectly as ever, but he felt a dislike for his wife and children which he had never felt before. He did not want them about him, and wanted the constant presence of his mother. This may have been nothing more than an excessive degree of the peevishness often observed in invalids; the feeling subsided as improvement began. Sexual power was lost, though desire was not much altered. First began to regain some power of movement in bed in about six weeks from the onset, and by the end of two months could stand by supporting himself by holding on to the backs of two chairs.

I am unable to get any information regarding the state of the reflexes while the patient was in bed, but the cutaneous reflex and ankle clonus were well marked when he began to walk, as well as spastic symptoms. While sitting in a chair, with the ball of the foot on the ground and the heel unsupported, marked clonus would be produced. If he would step with his bare foot on a small piece of coal, he would be thrown down by the violence of the contraction thus produced, and his legs would become rigid when he suddenly straightened them out in bed.

Inco-ordination was first noticed a few months after he began to walk, though he thinks it may have existed earlier. Inability to walk in the dark first attracted the patient's attention. Patient thinks that, on the whole, there has been a sort of interrupted improvement extending from a period about six weeks after the onset down to the present time, though slower within the last year than before.

The subjective influence of custom and the increased facility gained by practising locomotion under difficulties must all be taken into account in considering the patient's estimate. He has, however, been, for nearly six months past, under the observation of my assistant, Dr. Slater, at the Post-graduate Medical School, who has watched and studied the case with great care, and he reports distinct improvement within that period.

Present Condition.—Patient is well nourished, and, with the exception of a somewhat capricious appetite, his general health is good. Probably owing to some weakness of the abdominal muscles and some blunting of sensibility of the rectum, he has to stimulate this latter organ by the insertion of his finger in order to effect a movement of the bowels. The sphincters are still somewhat weak, as he says it would be difficult, or even impossible, for him to retain a loose passage after taking physic, and he has to make haste when he feels the desire to urinate. The gait is typical of ataxic paraplegia; the feet are kept far apart; the legs are rather dragged after the body, and the toes scrape the ground. There is considerable jerkiness in any movement of the leg, and he cannot stand with the eyes closed.

Myotatic irritability, as evidenced by the knee-jerk and ankle clonus, is considerably exaggerated, and so is the cutaneous reflex from the soles, though it is not developed by a slight touch. A slight prick of a pin produces a sharp contraction. Cremasteric, gluteal, and abdominal reflexes could not be obtained. There is no muscular atrophy in any situation, no tendency to trophic changes, and electrical excitability to both currents is normal in quality, though possibly reduced somewhat in quantity.

The patient thinks the subjective feeling of numbness—exactly as if the parts were asleep—is the same as at the time of the onset. The sensibility to touch and temperature changes is distinctly blunted. When a test-tube, filled with hot water, was firmly applied to any part, he promptly responded correctly, but when a tube of exactly the same size and shape, filled with cold water, was applied, there were many parts below the knee, upon both legs, where he could not be certain if it was hot or cold; and in an oval space about three inches in the longest vertical diameter, on the inside of the left calf, he frequently pronounced a cold body hot. The prick of a pin produces pain promptly, and, he thinks, natural in quality.

Tactile sensibility and sensibility to temperature changes improve gradually from the knees to the uppermost limit in the vicinity of the umbilicus, which comprises a zone of doubtful territory about two inches wide. That is, when the finger is passed slowly either upward or downward, and the patient is requested with closed eyes to indicate when the limit is reached, he will say, "right about there" when the finger is arrested anywhere in a zone as above described.

Though, while the patient has been under my observation, the left pupil has generally been a trifle larger than the right, I have been unable to discover any conspicuous defect in vision, movement, the fundus, or ocular reflexes that would tend to throw any light on the case.[1]

I should have stated that throughout the period of headache preceding the onset of paralysis, the patient had ulceration of the scrotum, which itched intolerably, and which he habitually scratched. When the paralysis supervened his attention was no longer directed to the scrotal itching and the ulcer healed, leaving a cicatrix which I would not be able to pronounce positively specific.

An acute process commencing at the lower extremity of the lumbar enlargement and rapidly progressing to its upper extremity—or to the eleventh dorsal pair slightly above the upper extremity—and there ceasing, and then commencing between the seventh and eighth cervical pair at the bottommost part of the functionally important region of the cervical enlargement, and manifesting the same progressive tendency that was shown in the lower segment, would seem to lend particularly strong support to the etiological hypothesis put forward by Gowers, that this disease may be due to a toxic or other influence acting upon the fine filamentous terminations of the upper segment in the gray matter of the cord.

That the process stopped near the level of the eleventh pair to continue near the eighth—if possibly it did not begin in the latter before it had entirely ceased to progress in the former situation—would indicate a special susceptibility of the parts in proportion to their distance from their centre—the brain—their functional complexity and importance, and the distance from them and from their centre of the parts to which the special modes of energy they severally convey is ultimately conducted.

That is, it would be easy to understand how a comparatively coarse mechanism might suffice to distribute the necessary energy to the abdominal muscles, while an exceedingly fine and complex mechanism might be required to supply the hand, finer indeed than that for the foot; but the increased distance of these latter filaments from their centre might give them the priority in point of vulnerability.

I shall refrain from attempting to account for the nausea, vomiting, and hiccoughing, as well as the antecedent headache.

The mode of onset of the ataxic paraplegia in this case, together with the fact that its course has been regressive rather than progressive, would, according to the literature of the subject, remove it from the category of ataxic paraplegia proper, though the symptoms are clearly typical of that disease.

[1] My colleague, Dr. W. Franklin Coleman, examined the eyes very carefully, and found some varying insufficiency of the internal recti.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, March 22, 1890.

THE WEIGHT OF INFANTS AND THE AMOUNT OF FOOD.

IN an article recently published in the *New York Medical Journal* attention is called, by Dr. A. Siebert, to the necessity of more exactly graduating the amount of food which bottle-fed infants should take. Dr. Siebert insists that, while there has been a great deal of study of the subject of the quality of milk, its amount has been left in general to the judgment of the mother or nurse. Quite recently, to be sure, Escherich gave tables of the amount of food, arranged according to the age of the child. Dr. Siebert, however, thinks that it is not the age but the weight of the child which should determine the amount of food, and he cites Rotch as saying: "Of the different causes which regulate the gastric capacity, the *weight* of the infant has the greatest influence, and it is perfectly possible for a poorly developed infant of small weight to have a gastric capacity no greater than a normally developed infant of half the age."

Boedert, also, in support of this view says, in Vogel's text-book: "In case the digestion is very easily disturbed, a more exact regulation of diet would be necessary, so as to give two hundred cubic centimetres of properly diluted milk to every kilo of the child's weight."

Having convinced himself upon, as it seems to us, rather slender data, that the weight of the child is the main factor in determining the food amount, a table has been prepared accordingly.

The chief items in this table are shown here.

Child's weight in pounds.	Size of bottle.	Amount.		
		Of milk.	Of gruel	Of sugar.
6, 7, and 8.	13 ounces.	1 ounce, or 2 tablespoonfuls.	2 ounces, or 4 tablespoonfuls.	½ teaspoonful.
9 and 10.	4 ounces.	1½ ounce, or 3 tablespoonfuls.	2½ ounces, or 5 tablespoonfuls.	½ teaspoonful.
11, 12, 13, and 14.	5 ounces.	2½ ounces, or 5 tablespoonfuls.	2½ ounces, or 5 tablespoonfuls.	¾ teaspoonful.
15 and 16.	6 ounces.	3¼ ounces, or 7 tablespoonfuls.	2⅝ ounces, or 5 tablespoonfuls.	¾ teaspoonful.
17 and 18.	7 ounces.	5 ounces, or 10 tablespoonfuls.	2 ounces, or 4 tablespoonfuls.	1 teaspoonful.
19 and 20.	8 ounces.	All milk.	.....	1 teaspoonful.

As the table indicates, a series of six bottles of different sizes has been prepared, on each is stamped a line indicating the amount of milk to be put in it and the weight of the child for which each one is to be used. The bottles are fitted with rubber corks ingeniously fixed with vents at the side, so that the milk can be sterilized and then the bottle sealed without removing the cork. A tray to hold the bottles is so arranged that it can be placed in a sterilizer or in an ordinary kettle.

Dr. Siebert's device will do a service, no doubt, in directing attention to the subject of the exact dosage of food for infants. It is unlikely, however, that the profession will accept without more evidence the dictum that the weight of the child is the sole or dominant factor in determining the amount of food, though no doubt it is an important one.

A CASE OF PSYCHIC PARESIS, WITH AUTOPSY.

AMONG the most interesting and yet most puzzling cases of nervous disease with which the physician has to deal are those in which disorders of volition form the most prominent symptoms. Disturbances of this nature are many of them functional, depending on no local anatomical change; the trouble originates from some abnormal condition of the circulating fluids, or is due to some reflex irritation. The broad-minded physician is, however, very cautious in referring cases to this category, since post-mortem examination frequently reveals extensive disease of the brain where none was suspected during life. Instead of putting the case aside with a label of "Kidney Disease," "Softening of the Brain," "Syphilis," "Hysteria," or "Change of Life," and thinking no more of it, he prefers to note carefully the exact symptoms exhibited, and to seek, by the aid of modern writings on brain localization, to reason out as accurately as possible the probable seat of the trouble, in the hope that, if the issue is fatal, a post-mortem may verify his diagnosis.

A case of this nature, which will interest the reader because of its resemblance to obscure cases in his own practice, is related by Dr. Inglis in the "Proceedings of the Detroit Medical and Library Association," 1889.

The patient, an adult male, whose history as regards length of illness, habits of life, or possible injury were wholly unknown, was brought to the sanitarium in a state of mental torpor with apparent paresis of the right side. No abnormality could be found in temperature, pulse, sight, hearing, condition and reaction of the pupils, in the appearance of the surface of the body, nor in the state and functions of its various organs. The urine showed no signs of either nephritis or diabetes. There were no indications of syphilis. He lay continuously upon the back, giving no evidence of intelligence, occasionally drawing up the left leg or putting the left hand to the face or head, but never moving the arm or leg of the right side.

His response to questions or commands was, however, of a very peculiar nature. He evidently understood them, but could bring his mind to bear on a subject only for a moment. He would put out his tongue as requested, but would fail to withdraw it. He would, when asked to shake hands, grasp with his left hand and forget to let go. His replies to questions were quite appropriate, but monosyllabic. The paresis of the right side was not a true paresis, for he could, when specially ordered, perform any desired movement with the right arm or leg as well and as strongly as with the left.

It was decided that the lesion, whatever it might be, did not involve either the motor area of the cortex or the motor conducting paths; that, since it interfered with

volition, producing a psychic paresis, it must affect the frontal convolutions of the left cerebrum; that it must involve the right side also, since in many cases hemiplegia, even when it produces complete loss of motor and sensory power, and throws the frontal lobes out of function, does not disturb the mental faculties, save as concerns speech. In the absence of a history of the patient and of his disease, no opinion could be formed of the nature of the lesion.

The patient remained in the same condition for some time (how long is not stated) and then failed rapidly, with increasing stupor, stertorous respiration, and filling up of the lungs. An exploratory incision was made at a spot where the skull presented a depression, and the bone was trephined, but nothing abnormal was detected except venous congestion of the underlying brain. The patient died shortly afterward. At the autopsy an infiltrating tumor—yellowish, gelatinous, but tolerably firm—was found in the white substance of the left anterior lobe, measuring about an inch in each diameter, and located three-fourths of an inch below the upper surface. The lateral and posterior part contained an irregular cyst of yellow, non-purulent serum. The tumor lay chiefly under the middle frontal convolution. It was distinctly separated from the cerebral ventricle, which, with its contents, was normal. The cerebral tissues, except those next to the tumor, were healthy.

A smaller, firmer tumor, without cystic development, was found in a corresponding position on the right side.

On the surface of the corpus callosum, when the hemispheres were drawn apart, was seen a discolored spot half an inch in diameter, and in its substance there was a small infiltrating deposit of the same neoplasm as that which had been found in the hemispheres.

A BID FOR IGNORANT DOCTORS.

A BILL now before the Albany Solons, and presented by a member from this city, is entitled, "An act to repeal the Statute requiring the Preliminary Education of Medical Students." It has already been advanced to the order of third reading. From all appearances it is a trap, set in a quiet way, as is the case with so many similar legislative measures.

For many long and weary years the battle waged over just this point, and finally the friends of higher medical education won, as they thought, a decisive victory. But it seems that perhaps it was not the Appomattox of medical ignorance after all. There is evidently on the other side an Old Guard that may die but will never surrender. It becomes us, therefore, to remember the price of liberty and exercise the necessary vigilance.

In another sense there need be no surprise felt at the proposed action. The number of men desiring to enter the medical profession in this State is large. The prevalent overcrowding does not deter them in the least. A certain percentage of them are unfortunately not overscrupulous about the methods they take to obtain their degree, nor the standard of the institutions at which they study. Unfortunately, again, there will always be a certain number of older men who, under the guise of a medical college, legally created, will receive them without any inquiry as to their fitness, satisfy them with a poor quality of instruction, and finally turn them loose upon the community. This being the case, it is not surprising that these denounce the existing law requiring the possession of an academic degree or a Regent's certificate as a preliminary to medical graduation. They find their occupation gone. The rôle of *Othello* does not suit them.

It is a great pity that such a question as this should have to bear the buffetings of political parties. If the chief magistrate were a man whose career was such as to rank him among the avowed friends of higher education we might feel no fear that any repeal measure would be allowed to become a law. We cannot believe that the majority of the legislators would pass any such measure as the one proposed. The continuance of the present well-regulated statute is a matter affecting every person in the whole State. It has no political bearing. It is a measure for the common good. We are particularly surprised that the sponsor of the proposed repeal should be a man whose previous connection with metropolitan journalism has been so creditable. He, of all men, should know the necessity not only of keeping the standard of medical education at its present height, but of raising it still higher.

There is reason for great watchfulness on the part of the State, and various county societies. *Nulla vestigia retrorsum.*

CEREBRAL SURGERY.

CEREBRAL surgery will soon fall into disrepute unless better results are reported than we have observed of late. Two sessions of the Academy of Medicine of St. Louis, an organization that is new to us, were consumed in discussing the case of a young man who suffered from hemiplegia, aphasia, Jacksonian epilepsy. The reporter of the case observed that: "The latest investigations seem to locate the centre of amnestic aphasia in the first convolution of the temporal lobe, while the centre of motor aphasia seems to be located more on the other side of the fissura Sylvii, in the lowest convolution of the frontal lobe of the left side. So the affection of the speech, so far as localization goes, depends on the first convolution of the temporal and the third convolution of the frontal lobe."

The patient had otorrhœa, however, and so it was decided that he probably had an abscess in the temporal lobe. He was trephined, and promptly died. The autopsy showed the presence of three tumors in the central convolutions. Dr. Bernays, the surgeon, thinks that his operation should be called exploratory craniotomy, and is satisfied that he will do it very frequently. After perusing with much care and interest the reports of the proceedings of the St. Louis Academy of Medicine regarding this case, we must confess that the most creditable thing about them is their candor.

A second case of cerebral tumor is reported by Dr. J. F. Morse, before the San Francisco County Medical Society. Here the tumor was correctly diagnosticated and located. The patient died, however, within twenty-four hours after operation.

Dr. J. O. Hirschfelder reported a third case of cerebral tumor in which the attempt to remove it was followed by death.

We refer to these cases, not with any intention of re-

flecting upon the surgical skill of our colleagues in Missouri and California, but to show that better results must soon be gotten or cranial surgery will fall into great disrepute. Among four other cases of brain tumor reported in 1889, only one was successful. Cerebral surgery for the relief of tumors, abscesses, etc., is apparently the most difficult of all forms, and success only comes with experience and the most thorough knowledge of its technique.

News of the Week.

The Society of the Alumni of Bellevue Hospital, one of the most energetic and progressive of our younger medical organizations, proposes to hold a reunion on April 8th and 9th. The Society consists of physicians who have served as internes at Bellevue Hospital, and has nothing to do with the college, as some might suppose from the name. The programme of the reunion is as follows: On the evening of April 8th a paper will be read by Dr. Charles Phelps, followed by a discussion, in which a number of the prominent surgeons of New York will participate. On Wednesday morning a surgical clinic will be given by Dr. L. A. Sayre, at the Bellevue Hospital; and on Wednesday afternoon a scientific meeting will be held at the Mott Memorial Hall, No. 60 Madison Avenue, at which a number of interesting papers and discussions will be presented, including a paper by Dr. Reuben A. Vance, of Cleveland, on "The Ultimate Results of Injuries to the Hip," and a discussion on "Transient Glycosuria," and "Delicate Tests for Sugar," introduced by Dr. Brandeth Symonds. On Wednesday evening a banquet will be given at the Hotel Brunswick. On Thursday morning Dr. W. T. Lusk will hold a gynecological clinic at Bellevue Hospital.

The Forms of Anæmia.—Oppenheimer and Gräber formulate the following pathological and nosological rules: "Number of corpuscles and hæmoglobin both diminished — acute and chronic anæmia. Number of corpuscles diminished, hæmoglobin relatively increased —primary chlorosis or pernicious anæmia. Number normal, hæmoglobin diminished—chlorosis." In severe cases of chlorosis, with tendency to faintness, headache, heart symptoms, and œdema without albuminuria, the hæmoglobin vary, according to Oppenheimer, from 30 to 50 per cent. He also says that in simple ulcer of the stomach the blood is normal, except where there has just been hæmatemesis, but in carcinoma of the stomach both the number of the corpuscles and the hæmoglobin are subnormal. Pale girls sometimes take iron for a long time without any visible improvement. Dr. Oppenheimer finds that such patients are not anæmic, but chlorotic from some uterine or other affection, so that when the blood is found to be normal it is advisable to make a vaginal examination!

The University of Louisville held its fifty-third annual commencement, February 28th, and conferred degrees on one hundred and forty-five students, it being the largest class ever graduated. We hope it was also the best. One hundred and forty-five doctors in one year is a considerable responsibility for a single institution.

The Soft Chancre, says M. P. Coulon, is disappearing from Paris and going to the provinces. During last summer's exposition, however, the crowds of provincials brought in an unusual number of chancroids.

About Seventy Discontented Members of the British Medical Association have resigned. The list includes the names of Thomas Bryant, Ch. Heath, Berkley Hill, Eustace Smith, Edmund Owen, Matthews Duncan, and Frederick Treves.

The Medical College of Ohio held its commencement on March 6, 1890, and graduated ninety-one men. We are glad to notice that the Faculty announce that hereafter the course will be extended to four years.

Starling Medical College held its forty-third commencement on March 6th, graduating thirty-nine men. The largest class in thirty-eight years has been in attendance.

A Bequest to the Johns Hopkins.—Mrs. Caroline Donovan, who died recently in Baltimore, left a legacy of $100,000 to the Johns Hopkins University.

Small-pox in Meriden.—There is said to be an epidemic of small-pox in Meriden, Conn., and the physicians are reaping a harvest from the vaccinations which they are called upon to perform. Several reported over three hundred vaccinations each in a single day. The number of reported cases of small-pox since the epidemic began is between thirty and forty.

A Name Wanted.—If the correspondent who recently sent the report of a case to the MEDICAL RECORD, but forgot to send his name, will supply the deficiency, we shall be glad to publish his case.

Mississippi State Medical Association.—The next annual session of the Mississippi State Medical Association will be held in Jackson on April 16th.

Florida State Medical Association.—At a meeting of the Executive Committee of the Florida Medical Association, held in Jacksonville, February 20th, it was decided to change the place of the annual meeting from Key West to Ocala. This was deemed best after consultation with the President of the State Board of Health, lest quarantine regulations might interfere with the meeting at Key West. The meeting will be held in Ocala on April 8th, the session being opened in the Opera House at 3 P. M.

Dr. Charles J. Nordquist, of Tuckahoe, N. Y., was killed a few days ago by a train on the Harlem Railroad. He was driving from Mount Vernon to his home, and while crossing the track his phaeton was struck by the engine, and he was thrown out and killed. Dr. Nordquist was a native of Sweden, his father having been physician to Bernadotte, King of Sweden. He came to America in 1843 and settled in Tuckahoe, where he has lived ever since. During the war he served as Medical Inspector of the First Army Corps, and was present in many of the most important battles. He leaves a wife and two married daughters.

Death from a Mad Horse Bite.—Dr. J. T. Aspy, of Columbus, Ind., died recently from what was reported to be hydrophobia. He was bitten by a mad horse a few days before his death, the horse having been bitten previously by a rabid dog.

The North Philadelphia Hospital.—A charter has been obtained from the Pennsylvania Legislature for a new hospital in Philadelphia, which will be known as the North Philadelphia Hospital. The incorporators have secured a large three-story stone building, 3328 North Broad Street, containing fifteen rooms, which is being put into proper condition for hospital purposes. Six beds will be prepared for use immediately on the opening of the institution, which will probably be during the present month. It is said that there are numerous manufacturing establishments in the neighborhood, in which many accidents occur, but that there are no hospitals within convenient distance, and that consequently this hospital will supply a real want.

A Brooklyn Society for the Relief of Cripples.—A meeting was held recently in Brooklyn for the purpose of discussing the condition of the crippled and deformed children in that city, and to consider plans for their relief. Several of the speakers at the meeting stated that many of the children in Brooklyn who were suffering from chronic joint diseases were taken over to New York for treatment, notwithstanding the facilities offered at home by the Long Island College and the Orthopedic Dispensaries.

Brooklyn Hospital Saturday and Sunday Association.—The receipts of this association for the present year were $5,398.24, of which $965.17 was contributed through the boxes.

Medical Legislation in Oregon.—The Governor of Oregon has vetoed the Power Medical Bill, passed recently by the Legislature, giving, as one reason, that it did not recognize sufficiently the different schools of medical practice. A new bill has now been introduced, which, it is hoped, will prove acceptable to the Governor.

Dr. G. W. Wilkinson, of Dakota City, Neb., has been appointed superintendent of the Norfold Insane Asylum. Dr. Wilkinson is one of the earliest settlers in the State, having resided in Dakota City since 1856.

A Bill to Regulate Medical Practice in Rhode Island is now before the Legislature of that State. The first section of the act provides that only registered physicians shall be allowed to practise medicine in this State, and section 2 is as follows: "Every person in order to be a registered physician within the meaning of this act shall be either a graduate in medicine or a practising physician. Graduates in medicine shall be such as have obtained a diploma from a regularly incorporated school or college of medicine, and shall have presented to the State Board of Medicine satisfactory evidence of their qualifications. A practising physician shall be deemed to be a person who for the —— years next preceding the passage of this act has continuously practised medicine in this State, and who shall have presented to the State Board of Medicine satisfactory evidence of his qualifications, and any other person who shall have presented to the State Board of Medicine satisfactory evidence of his qualifications to practise medicine."

The Camden Medical Society has appointed a committee to urge upon the New Jersey legislature the passage of the Kalisch bill, providing for the establishment of a State Medical Examining Board.

The Medical Library of the University of Pennsylvania is said to be growing very rapidly, having received numerous gifts of books and money. The two principal donors are Dr. Alfred Stillé, who presented a collection of books, numbering 3,000 bound volumes, and 5,000 unbound volumes and pamphlets, and Dr. William Pepper, who more recently gave the greater portion of his own medical library; $15,000 in money has also been received, one-half of which has been expended in the erection of the new library building, while the other half is to be retained as the nucleus of an endowment fund for the purchase of books and medical journals.

Medical College Commencements.—The following are a few of the colleges which have held their commencements this month: Atlanta Medical College, Atlanta, Ga., 51 graduates; College of Physicians and Surgeons, Keokuk, Ia., 61 graduates, five of whom were women; Georgia College of Eclectic Medicine, Atlanta, Ga., 16 graduates, including one woman; Howard University Medical School, Washington, D. C., 26 graduates, one of whom was a woman; Medical College of Ohio, Cincinnati, 91 graduates; Miami Medical College, Cincinnati, 31 graduates; Pulte Medical College, Cincinnati, 16 graduates; Ensworth Medical College, St. Joseph, Mo., 14 graduates; Woman's Medical College of Pennsylvania, Philadelphia, Pa., 40 graduates; Kansas City Medical College, Kansas City, Mo., 16 graduates; Iowa College of Physicians and Surgeons, Des Moines, Ia., 5 male and 2 female graduates; Western Reserve Medical College, Cleveland, O., 30 graduates; Long Island College Hospital, 57 graduates, one of whom was a Chinaman.

Tennessee State Medical Society.—The fifty-seventh annual session of the Tennessee State Medical Society will be held at Memphis, April 8th, 9th, and 10th, at the Gayoso Hotel.

Another Impostor.—We are informed that there is a man at present in the city who makes his living by calling upon physicians in the evening, representing himself to be the brother of a well-known physician of Elizabeth, N. J. His story is that he has suddenly found himself without a cent, and as all the downtown offices are closed, and his friends have gone home, he is obliged to request the loan of a dollar. The man is rather below middle height, of fair complexion, with a brown mustache, and very well dressed. He made the mistake of calling a second time upon the correspondent, who sends us the information for the benefit of others who may be visited and importuned for a small loan.

Iowa State Medical Society.—The thirty-ninth annual session of the Iowa State Medical Society will be held at Des Moines on Wednesday, Thursday, and Friday, April 16th, 17th, and 18th.

The United States Pension Board, at Northampton, Mass., lately reorganized, now contains two homœopathic practitioners.

The South Carolina Board of Medical Examiners held an examination of applicants for license to practise medicine in that State on March 5th. Of the eighteen who applied for license twelve were successful, four were rejected, and two will be re-examined at the next meeting, in April.

St. Mark's Hospital.—The hospital at 66 St. Mark's Place, formerly known as the Association Hospital, has recently been incorporated under the name of the St. Mark's Hospital of New York City. The certificate of incorporation contains the condition that the members of said corporation shall adhere to the theory of medical or surgical treatment known as the regular school, and the system of practice of medicine or treatment which shall be applied in said hospital shall be such as is used by regular practitioners and known as the regular-school system. The Board of Managers for the first year are Eugene Lewis, Max Ruttenan, D. McLean Shaw, Dr. Leonard Weber, Dr. Henry J. Garrigues, Dr. Cæsar A. Van Ramdohr, Dr. Carl Beck, Dr. Emil Neumer, and Dr. Herman J. Boldt. The hospital was formerly supported by contributions from various relief associations, lodges, and the attending medical staff, but by means of this reorganization it is hoped that it will be placed on a better financial footing. Most of the patients are treated free.

Cincinnati Academy of Medicine.—Dr. C. D. Palmer has been re-elected President of the Academy of Medicine of Cincinnati. The membership of the Academy is 164, and is growing steadily.

Measles in Minneapolis.—The Board of Health in Minneapolis is having a hard time endeavoring to restrict the spread of measles, which is epidemic in that city. The trouble is the want of funds, and the city council persistently refuses to increase the appropriation.

Death of Old Andy the Janitor. — Old "Andy" (Andrew Loughlin), the faithful janitor for so many years of the College of Physicians and Surgeons, New York, died March 14th. When the College moved from Twenty-third Street he was too feeble to perform the duties in the new building, and he was consequently retired by the faculty and made an emeritus. He drew his regular wages, as a pension. He moved up near Fifty-ninth Street, and for some time came occasionally to the College and sat in a chair near the front door—as it were playing janitor. For the last year he has been too feeble to do even this. He outlived his wife, and "Tommy," his son. Many of our readers, boys of twenty-five years ago, will remember old Andy, and associate him with pleasant recollections of college life. Good-by, Andy, we are young again when we think of you.

Reviews and Notices of Books.

Wood's Medical and Surgical Monographs. Vol. V., No. 2. New York: William Wood & Co. 1890.

In the February number of this now well known and deservedly popular series of monographs, there is a very interesting and suggestive paper by Dr. A. Haig on "The Formation and Excretion of Uric Acid, as Elucidating its Action in the Causation of Disease." Other articles in the volume are: "The Initial Stages of Consumption; the Nature and Treatment, Including Dietetic Suggestions," by Dr. Horace Dobell, of London, and "Ectopic Pregnancy and Pelvic Hæmatocele," by Mr. Lawson Tait. The first two numbers for this year give promise that the high mark of usefulness reached during the first year of publication will be at least equalled, if it is not surpassed, by the series for 1890.

Contributions to the Surgical Treatment of Tumors of the Abdomen. Part II. Electricity in the Treatment of Uterine Tumors. By Thomas Keith, M.D., LL.D. Edin., and Skene Keith, F.R.C.S. Edin. Pp. viii., 255. Edinburgh: Oliver & Boyd, Tweeddale Court. London: Simpkin, Marshall, Hamilton, Kent & Co., Limited. 1889.

This unassuming little volume possesses more than ordinary interest, as it represents the personal experience of a surgeon who, after achieving remarkable success in the radical treatment of uterine fibroids, has deliberately renounced laparotomy in favor of the method introduced by Apostoli. With characteristic candor and modesty, Dr. Keith indulges in no extravagant generalizations as to what he has done. The book consists of a series of plain, unvarnished statements of clinical facts, from which the reader is at liberty to draw his own inferences. One hundred and six cases are recorded at length, certainly a sufficiently large number to serve as an important addition to the literature of the subject. Discredit has been brought upon Apostoli's method by those whose experience has been too limited, and their experience too imperfect to carry weight with the sceptical; no one can afford to treat lightly the statements of the able and conscientious authors of this book. It is impossible to give the reader an idea of its scope, because, unfortunately, there is no attempt at summarizing. Certain explanations in the preface indicate the routine methods adopted. "About half of the cases that presented themselves were sent away without any treatment, simply because the tumors were giving little or no trouble, or they were near the menopause, when no treatment was necessary." This is a sufficient reply to recent English criticisms of Keith's statistics. "We know now," is stated in another place, "that the cases best treated are those who are suffering much from hemorrhage—the more the better—cases in which something must be done; cases in which, two or three years ago, the question of operation of some kind would have been considered by us." In conclusion we read the sturdy declaration: "We believe it to be the right treatment, and our patients must get it, however great the inconvenience and monotony of it may be to ourselves. Though our results after hysterectomy show the lowest mortality of any yet recorded, and though we have had but a single death after removal of the ovaries for fibroid in almost one hundred operations, we reject even the minor operation in favor of Dr. Apostoli's treatment, and we reject hysterectomy altogether, on account of the mortality that has hitherto attended it all over the world."

Artificial Anæsthesia: A Manual of Anæsthetic Agents and their Employment in the Treatment of Disease. By Laurence Turnbull, M.D., Ph.G., Aural Surgeon to the Jefferson Medical College Hospital, etc. Third edition. Revised and enlarged. With illustrations. Pp. 531. Philadelphia: P. Blakiston, Son & Co. 1890.

The third edition of this valuable manual contains much new matter, and in its present form is one of the most attractive works on this important subject, of which the author strikes the key-note when he says in the preface: "Human life is too valuable at the present day to be destroyed by incompetent administrators of such beneficent, yet death-giving agents." No less than nine chapters are devoted to cocaine, and over three hundred pages to ether and chloroform. We can hardly excuse the author for not absolutely condemning rectal etherization, a procedure which has resulted so disastrously in this city. The relative merits of chloroform and ether are thoroughly discussed, and the author summarizes in a few forcible words, in which he takes a decided stand in favor of the latter anæsthetic. We wish that this little volume might be placed in the hands of every interne who thinks that he knows everything that is worth knowing about the administration of ether.

Through the Ivory Gate: Studies in Psychology and History. By William W. Ireland, M.D. 8vo, pp. 311. Edinburgh: Bell & Bradfute. New York: G. P. Putnam's Sons. 1889.

This book is a companion to the author's well-known work entitled "The Blot upon the Brain." It is a continuation of certain chapters in the latter, a more detailed development of the insane biographies of Swedenborg, Mohammed, Joan of Arc, Mohammed Toghlak, and others. Some of our more recent paranoiacs receive minute and careful description at his hands, and to those interested in such subjects these psychological studies of the lives and deaths of King Ludwig of Bavaria, Charles J. Guiteau, and Louis Riel, will prove absorbingly entertaining. The title of the book originates from some of the ancient poets, who were wont to say that the deluded were visited by spectres which came through the Ivory Gate. Thus Horace (Carm. III., Ode 27): "Do I, in the waking state, deplore the baseness of my fault, or does some vain image, fleeing from the Ivory Gate, delude me, innocent of any misdeed?"

The National Medical Dictionary: Including English, French, German, Italian, and Latin Technical Terms used in Medicine and the Collateral Sciences, and a Series of Useful Data. By John S. Billings, A.M., M.D., LL.D. Edin. and Harv., D.C.L. Oxon., Member of the National Academy of Sciences. Surgeon U. S. A., etc. With the collaboration of W. O. Atwater, M.D., Frank Baker, M.D., S. M. Burnett, M.D., W. T. Councilman, M.D., James M. Flint, M.D., J. A. Kidder, M.D., William Lee, M.D., R. Lorini, M.D., Washington Matthews, M.D., C. S. Minot, M.D., H. C. Yarrow, M.D. In two volumes. Philadelphia: Lea Brothers & Co. 1890.

It is a very difficult matter to form a just estimate of any work of reference, such as an encyclopædeia or a dictionary, except by actual and long-continued trial, for the words that one would need to have explained will naturally not be thought of in the course of an ordinary examination. But as the notice of the book before us could not in justice be deferred until practical experience had demonstrated its true value, we have tested it as carefully as was possible by comparing it with other dictionaries, and by checking off the technical terms found in two articles in German and Italian. We will confess that we had expected to find many omissions of foreign words, but we were agreeably disappointed in this respect. There were omissions, it is true, but not many, and most of the absent words in the German were compounds, the derivatives of which were generally to be found in their proper places. We cannot, however, approve of the way in which the German words have been classified in respect to the modified vowels. These vowels are printed ä, ö, ü, but the words containing them are arranged as if the vowels were printed a e, o e, and u e. Thus *Lahmen* is found on p. 29, volume ii., while *Lähmen* occurs on p. 28, thirty-five titles, filling two columns, being found between the two words. This is not the usual arrangement in dictionaries, and leads to a good deal of confusion in a hurried search after a meaning. The French portion, and the German also, might have been made a little more complete had the compiler consulted Palmer's dictionary. By the majority of physicians, however, the work will be consulted only for the English and Latin terms, and this part is excellent. We have devoted considerable time to the comparison of the book with Dunglison's, Thomas's, and the first volume of Foster's dictionaries, and we have been unable to detect any serious omissions. The definitions are brief and clear, the compiler's aim seeming to have been, very properly, we think, to exclude any semblance to an encyclopædic character. The main fault, and the only serious one, is the size of the work. A two-volume work of reference is much less convenient than one in a single volume, and it is also more expensive. If smaller type had been used, the dictionary might probably have been compressed into one volume. It would not have presented as handsome an appearance, but it would have been more useful, and would have better suited the pockets of the great majority of medical practitioners. The objection to fine print would not be of weight in a work of this kind, for a dictionary is consulted merely, and not read, and the advantage of having it in one volume would have been great. However, we do not mean to be too critical, and this fault is not a fatal one, and to some may even be a recommendation. A number of useful tables in Vol. I. add to the value of the dictionary as a work of reference.

Aerztlicher Almanach. Von Med. Dr. Adolf Kállay. Vienna: Wilhelm Baumüller und Sohn. 1890.

This is the ninth year in which this popular medical almanac has appeared under the editorship of Dr. Kállay, and it loses nothing in interest by age. In addition to the usual information contained in similar works there are papers on the embryology of the kidney, treatment of heart diseases, and diabetes mellitus.

The Principles and Practice of Surgery: Being a Treatise on Surgical Diseases and Injuries. By D. Hayes Agnew, M.D., LL.D., Professor of Surgery, Medical Department, University of Pennsylvania. In three volumes. J. B. Lippincott Co. 1889.

The three large octavo volumes, profusely illustrated, and each averaging over a thousand pages, comprise the second edition of a work already well known and appreciated by all progressive students of surgery. In looking carefully through the large mass of material, many essential changes can be noted in arrangement and amplification, although the general plan of the previous edition is maintained. The author very truthfully says that during the last few years a spirit of extraordinary vitality has pervaded every department of medicine, and in none has it been more active than in that of surgery; that the doctrine of asepsis lies at the foundation of all the recent and splendid achievements wrought in abdominal, pelvic, and cerebral surgery, as well as in the improved management of wounds in general. Proving his faith by his works, he is a consistent aseptic, a firm advocate of the benefits of germicidal agents, and a safe counsellor in all other matters calling for sound judgment based on large experience. In a previous critical review of this work we dwelt somewhat in detail upon the general arrangement of its subjects and their methods of treatment, but this is obviously unnecessary at this time. Suffice it to say that the whole domain of surgery is thoroughly gone over, each of the different surgical diseases is treated in turn, based upon the individual experience of the author. The reader will be struck with the rare judgment shown in the apportionment of spaces to the different topics according to their relative importance, as well as to the judicious conclusions regarding what would appear to be the best treatment. If there is any criticism to be offered in this connection, it would refer to the section on Diseases of the Eye, in which some of the operations upon that organ are not given the attention and space which their importance might demand. Although admitting that the scope of the work would not allow of any change in this regard, it may become a question whether in future editions it might not be well to follow the example of other authors and omit the eye diseases altogether. Considering the number of subjects treated, and notwithstanding the size of the volume, it might seem almost paradoxical to say that the work, as a whole, is a well-condensed review of the present state of surgical science in this and other countries. It stands a monument of a careful study on a branch of medicine to which, as the author says, he has fondly devoted his life, and as such it must command the appreciation of his many admirers and fellow-workers.

Massage and the Swedish Movements. By Kurre W. Ostrom, Instructor in the Pennsylvania University Hospital, etc. Philadelphia: P. Blakiston, Son & Co. 1890.

In a simple and straightforward manner the author discusses in this small manual the various principles of massage and their practical bearings. His excuse for writing the book is that no previous treatises "have been sufficiently explicit" in their directions. We may admit this, but do not find any particular originality in these pages. The illustrations are a help. The writer is to be commended for his ideas in regard to placing massage in general under the control of the medical profession.

A Hand-book of Obstetrical Nursing, for Nurses, Students, and Mothers. By Anna M. Fullerton, M.D. 12mo, pp. 214. Philadelphia: P. Blakiston, Son & Co. 1890.

These pages comprise the substance of an annual lecture course delivered by Dr. Anna E. Bromall to the nurses of the Woman's Hospital of Philadelphia. They are to be commended for their simplicity and directness. In fact, it is hard to see how anyone of ordinary common sense could go astray in following the suggestions given for the various obstetrical emergencies. Thirty-four wood-cuts illustrate important points.

The Physician's Pocket Visiting-list and Ledger. By W. W. Hitchcock, M.D. Los Angeles, Cal.: E. K. Foster.

A combination of day-book and ledger, for pocket use.

Essentials of Obstetrics. By W. E. Ashton, M.D., Demonstrator of Obstetrics, Jefferson Medical College. Saunders's Question-Compend Series, No. 5.

We question whether there is as much need for manuals of this kind in obstetrics as in some other departments of medical study. The author has gone into all necessary details, and the student might well review the general field with the book.

The Animal Alkaloids. By Sir William Aitken, M.D., etc. Second edition. 12mo, pp. 112. Philadelphia: P. Blakiston, Son & Co. 1889.

These lectures treat of the ptomaïnes, leucomaïnes, and extractives in their pathological relations, and were delivered before the English Army Medical School. Frequent allusion is made to the original work of Gautier, Peter, Lauder Brunton, A. M. Brown, and others, and the originality of the author is shown in some interesting as well as practical deductions from the premises laid down.

A "Ptomaïne" is defined as an alkaloid resulting from putrefactive changes in dead animal tissues, and elaborated from proteid material. A "Leucomaïne" is an alkaloid which is a necessary result of a vital physiological process. These latter are being formed in the body constantly, and become toxic only when their elimination is interfered with. "Extractives" are certain azotized, crystallizable substances, undetermined, but more poisonous than either ptomaïnes or leucomaïnes.

In some detail is given a classification of these substances and of their chemical composition, tests, and modes of discovery and isolation. The latter part of the book is given up to a discussion of the practical bearing of all this knowledge on clinical medicine. As the author remarks, this new information will cause a new moulding of many of our ideas on the etiology of disease. We cannot follow out all the questions he propounds, but merely allude to one, viz., the origin *de novo* of some of the so-called germ diseases, *e.g.*: It is found that where men are crowded together, as on shipboard, in barracks, etc., that typhus fever will break out. What is the starting-point where we can entirely preclude the possibility of outside infection? It is, according to the new idea, the auto-infection of one man with his own leucomaïnes and extractives, the normal elimination of which has been interfered with by his temporarily bad environment—bad air, poor sewerage, crowding, etc. From him, as a focus, the disease spreads in the usual manner.

We unhesitatingly commend the book to anyone desiring a concise scientific statement of one of the most interesting of modern medical problems.

Text-book of Medical Chemistry. By Elias H. Bartley, M.D., Professor of Chemistry, Long Island Medical College. Second edition. Pp. 423. Philadelphia: P. Blakiston, Son & Co. 1890.

This book covers the usual ground gone over by medical students in their lectures and laboratory work on chemistry. It is purposely somewhat technical, for it is designed to aid pharmaceutical students also. Under the head of organic chemistry are sections on the natural organic bases or alkaloids, ptomaïnes, and glucosides. Considerable attention is given to physiological chemistry and toxicology. A few pages on urinary analysis are added, and the book closes with a valuable appendix and glossary.

The impression gained on examining the volume is most distinctly favorable. The grouping of topics is systematic, the definitions mathematically precise, and the pages bear evidence of accurate and careful scholarship. It is difficult to prepare a manual that shall be equally good for practitioners, students of medicine, and students of pharmacy, for their practical needs are diverse. So far as it can be done, however, the author has succeeded.

Organic Materia Medica. By John M. Maisch, Phar.D., etc. 8vo, pp. 539. Philadelphia: Lea Brothers & Co. 1890.

The author has been so long before the public as a writer on pharmaceutical topics that any formal commendation is entirely unnecessary. The present is the fourth edition of the book, which is profusely illustrated. It is needed especially by the druggist or physician purchasing drugs in the open market, as by its aid he can easily identify good and detect bad materials. Under each drug name is an epitome of its physiological action, with dose.

A Manual of Nursing. Medical and Surgical. By Laurence Humphrey, M.R.C.S., etc. 8vo, pp. 242. Philadelphia: P. Blakiston, Son & Co. 1890.

The writer is lecturer to the probationers at Addenbrooke's Hospital, Cambridge, and has in these pages formally published the substance of his lecture courses. In addition to what one might expect to find in such a manual, we have, in lay terms, a brief account of the symptoms and management of all the common diseases. The only criticism we have to offer is that it contains too much information for the average nurse to master, and entirely too many directions for a nurse to carry out, on her own responsibility, under any circumstances. If the book is meant for nurses of some years of experience, and not probationers, we would materially modify this criticism.

Prompt Aid to the Injured. By Alvah H. Doty, M.D., New York. Pp. 224. New York: D. Appleton & Co. 1890.

The writer is well known as a successful surgeon, and as being connected with one of the local regiments of the National Guard. In the field covered by "first-aid" literature it is difficult to say anything new outside of the practical points suggested by the experience of each individual writer. Dr. Doty's book is especially valuable to regimental ambulance corps, which usually have more or less personal instruction from their respective surgeons, and are therefore far more capable of appreciating intricate points than is the average layman. The opening chapters are devoted to a description of the body apparatus and the functions of the various organs. Then follow sections on bandaging and antiseptics. The last half is devoted to the detailed consideration of the various medical and surgical emergencies. The final chapter contains the Manual of Transportation now used by the United States Army.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, February 10, 1890.

ROBERT ABBE, M.D., CHAIRMAN.

Fracture of the Patella: Cases Illustrative of the Treatment.—A number of cases illustrating the result of treatment, by different methods, of rupture of the patella were presented by members.

First, THE CHAIRMAN presented a lady who had sustained oblique fracture, extending upward and inward, three years ago. Cutting down upon the fragments, he found their ruptured surfaces covered by a fringe of dense white fibrous structure, which it was necessary to remove. The fragments were then wired, a drainage-tube left in seven days—longer than he would leave it in another case since it probably increased the amount of stiffness of the knee. The patient had a very useful limb, with some stiffness.

Fracture of the Patella Four Times.—The second case presented by the Chairman was that of a man who during the past twelve years had sustained fracture of the patella four times. Dr. Phelps had wired the third fracture, and the fourth one took place at a point below. The healing after the fourth rupture left the fragments considerably separated, and the knee weak. For this reason Dr. Abbe divided the quadriceps and brought the fragments as nearly together as possible and wired them. The knee was now strong, the patient could walk up-stairs without support, but motion was not quite as free as it had been. The fragments were still separated an inch and three-quarters. There was a slight discharge from a small sinus, which, however, caused no inconvenience. The silver wire used at the time of the third fracture was still in position when he operated.

A specimen showing bony union between the two fragments of the fractured patella, which had been wired five years previously by Dr. Thomas M. Markoe, was presented by the Chairman. Suppuration had developed in the joint some time after the fracture and led to anchylosis. Death was due to pyæmia. The specimen was obtained at the autopsy.

DR. W. T. BULL presented nine patients whom he had treated without operation for rupture of the patella, whose histories were embodied in a paper which he read later.

Several Cases Treated by the Open Method.—DR. WILLIAM F. FLUHRER presented several patients, the first one being a man whose fractured patella was treated successfully by wiring, October, 1887, and ten weeks afterward he was able to flex the knee to a right angle, but on one occasion he over-flexed it and the fragments again separated. They were wired within twenty-four hours, and he acquired afterward apparently bony union with full use of the limb. The second patient was operated upon in 1885, and within seven weeks he had also acquired power of flexion beyond a right angle, but while pushing a chair before him he slipped and fell forcibly, causing refracture. It was wired within twenty-four hours, motion begun in three weeks, full power in ten months, with apparently bony union. The third case was in a man who fractured the patella by direct violence, and when he operated twelve days later the lower fragment was found completely separate and free beneath the skin. It was taken away. Silk-worm gut was used for the suture. The man acquired complete power of extension, but not quite complete flexion. In the next case, operated upon in 1885, there was some objection to giving ether. He introduced a needle and tried to lift the enfolded tissue from over the fractured surfaces of the bones, brought them then into apposition, and applied a plaster-of-Paris splint. Full power resulted.

Delayed Operation.—DR. WILLY MEYER presented a lad who had sustained fracture of the patella in December, 1888. He lay abed eight days. Dr. Meyer saw him ten weeks later, when he had a perfectly useless limb, not being able even to lift it. He cut down and brought the fragments in apposition, although with some difficulty, and wired them. The patient was permitted up to the present to flex the knee only to eighty degrees, and wore a splint. The limb promised to be a very useful one.

DR. W. T. BULL then read a paper (see p. 313) on "The Results of Treatment of Fracture of the Patella without Operation."

The Pendulum Swinging Again.—THE CHAIRMAN in calling for discussion upon the paper, remarked that the old story of the swinging of the pendulum was again applicable to operative treatment of fracture of the patella.

Can Bony Union be Obtained?—DR. L. A. STIMSON had wired the patella in one case after refracture, the former treatment having also been by metal suture, with reported bony union, but he found that while the fragments had been closely approximated, the union was not in reality bony, but fibrous. He did not think we were justified in claiming bony union for any case until the patella had been taken out and sawed in two. Liability to refracture was dependent, he thought, not upon the fact whether the union were either bony or fibrous, but rather upon partial fixation of the upper fragment from shrinkage of the lateral ligaments. In no case of wiring which he had seen had flexion to a right angle been possible within three months. Accidental over-flexion was pretty sure to produce refracture, and it would be compound because of adhesion between the bone and skin. There was growing distrust of wiring the patella. It was possible, however, that some more favorable method might be introduced.

That Fibrous Fringe.—This was found between the fragments at one part in a case in which an autopsy was obtained some time after union had taken place between the fractured parts sutured by silk, and yet he was able to obtain crepitus.

A New Method.—This he had performed in twenty-four cases, with good result, and without accident, excepting in two in which there was suppuration. It consisted in injecting cocaine at four points over the patella, two above and two below, some distance from the median line, and passing a silk suture, commencing at one point, going beneath the fibrous covering of the fragment down upon the bone, out at the point on the other side, reinserting the needle, passing to and out at the point below, again reinserting it and passing beneath the fibrous covering of the other fragment, and so around until the point of commencement was reached, when the ends were united and the fragments approximated. Splints were afterward employed. The method was simply on trial.

Believes in Mechanical Treatment.—DR. CHARLES MCBURNEY agreed with the views expressed in the paper. He had from the beginning felt strongly opposed to operative treatment except in compound and a form of oblique fracture. In one case of refracture, in which he feared there was a mass of intervening tissue, he wired the fragments, but in that instance, although the functional result was good, flexion was not complete. He had heard of a number of cases of very bad results following the operative method. In one anchylosis followed suppuration in both joints. In another there was suppuration and death. Thus there was undoubtedly a strong element of danger introduced by the operative method, while non-operative methods, with certain exceptions, gave very satisfactory results. He was satisfied if he got ligamentous union with not more than an inch and a half separation of the fragments, for function was sufficiently good. In backward and upward oblique fracture the open method was necessary. The longer the ligamentous union above an inch the more unfavorable the functional results.

To approximate the fragments he applied strips of

adhesive plaster over the quadriceps femoris, terminating in a strap, which he passed through a buckle similarly attached below. By leaving a fenestrum in the plaster-of-Paris splint, these straps could be drawn nearer together in the course of the case.

Dr. Charles Phelps said he had sutured the fractured patella in a number of cases, and had had no serious results, although in some there had been superficial suppuration. He intended sometime to collate them.

Dr. Carmalt, of New Haven, said his experience with the operative method was limited to two old cases in which there was a useless joint. He had never felt himself quite justified in operating in fresh cases where mechanical means brought the fragments in fairly good position. He preferred elastic to fixed extension.

Ten Operations without Suppuration.—Dr. Fluhrer said he had operated in ten cases of simple fracture of the patella in Bellevue Hospital without suppuration in any, although sepsis was known sometimes to be present in the ward. The method, he thought, was safe if antisepsis were strictly observed.

Dr. Joseph D. Bryant had wired four patellæ, in the first three instances to show how easily it could be done, and obtained a perfect success; in the fourth case he operated because he thought he should. Some caries of the bone took place along the wire, but it did not implicate the joint. He believed as he had expressed himself three years ago, to the effect that only in exceptional instances should operative methods supplant the mechanical.

Death from Suppuration.—Dr. Thomas Manley at one time, reasoning from the stand-point of the enthusiastic believer in antisepsis, entertained the view that the proper method of treating not only fracture of the patella but also fracture of long bones, was the open one. He tried it in the case of a long bone and the fragments did not unite. The last patella which he wired, and the last he expected ever to wire, was fractured last spring. Long-continued suppuration and finally death followed the wiring.

Dr. Spencer, of Watertown, had used only mechanical methods, and had heard of no complaints from his patients, all of whom were seen in private practice.

Dr. Willy Meyer thought it proper to wire the fragments if strict antisepsis could be observed.

The Chairman thought the operative method should be approached with great caution.

What Constitutes the Real Injury?—Dr. Hopkins, of Brooklyn, held the view, based on many dissections, that fracture of the patella bone itself was of little importance. It was rupture of the lateral tendons which constituted the real injury, and as these were distributed differently in different individuals, especial attention should be given to uniting them rather than to simply wiring the fragments of the bone.

Mechanical Treatment Best for the General Practitioner.—Dr. Bull, in his closing remarks, expressed his appreciation of the brilliant results following operative treatment when unattended by complications, but there was a danger connected with it which made it unsafe for general use. Regarding the details of the mechanical treatment, he placed quite as much confidence in a simple roller bandage in approximating the fragments as he did in adhesive straps spoken of by Dr. McBurney and Dr. Carmalt.

SECTION ON THEORY AND PRACTICE OF MEDICINE.

Stated Meeting, February 18, 1890.

Francis Delafield, M.D., Chairman.

The Mortality from Phthisis in Brooklyn and New York.—Dr. F. B. Westbrook read a paper with the above title, considering some phases of mortality of cities which are not usually discussed by systematic writers on phthisis. He enunciated the following propositions:

1. City life *per se* is not necessarily more detrimental to health or longevity than residence in the rural districts.

2. The relatively greater mortality observed in cities is the result of causes which should be equally efficient in whatever locality they might be operative.

3. The cause of the high death-rate among urban populations is to be sought in defective systems of sewerage; in the presence of large manufacturing establishments and other industries, in the pursuit of which many people are crowded together in a small space, with inadequate ventilation, or subjected to pernicious influences of irritating dusts and poisonous gases; in the existence of the lowest grades of tenement-houses; in the multiplication of groggeries, and the imperfections in the workings of the sanitary departments of municipal governments. A possible exception may be found in the greater difficulty in the limitation of the spread of contagious diseases in densely populated districts.

4. In addition to the above causes, which may fairly be said to be preventable, the mortality from phthisis in our American cities is greatly augmented by the presence of immigrants and their immediate descendants. The data at command are not sufficient to give any indications as to the number of generations for which this increased susceptibility to phthisis is or will be continued; but there can be no reasonable doubt that the process of natural selection and the intermingling of races will gradually obliterate it.

In the State of New York, he said, the deaths from consumption per thousand inhabitants is 2.5; in the city of New York, 3.5; and in the city of Brooklyn, 2.9. A fact of great importance, and one of which little had been said by the writers upon the subject, was, that while the total mortality of the large cities is somewhat excessive, there are differences among the various districts of the cities themselves, and that to such an extent that the death-rate of one ward may be two or three fold that of another. For instance, the death-rate from consumption in the Twenty-fourth Ward of Brooklyn in 1889 was 5.685, while that in the Twenty-third Ward was only 1.203, and the total for the city was 2.460. In New York the rate for phthisis in the Fifteenth Ward was 2.88, in the Twenty-third Ward 6.07, and in the Twelfth Ward 9.71; while in the entire city it was 3.318. The causes of these wide variations were the character of the location as regards soil and drainage, the presence or absence of the worst class of tenements, the presence of public institutions, particularly hospitals, and the nationality of the inhabitants.

Having given an analysis of the mortality from phthisis in a number of the wards of Brooklyn, and stated that the same analysis of the wards of New York would give a similar result, he said he would not undertake a defence of his second and third propositions, as their truth would probably be admitted by all. As to the influence exerted by the presence of foreign races undergoing the process of acclimatization, the number of immigrants in Brooklyn and New York was so great that its effect upon vital statistics was very decided, and easily computed in so far as our imperfect system of registration permitted of computation.

The tendency of races to die out when they are first transplanted to a country in which the conditions of life are widely different from those at home was well known. While, however, even a majority of the immigrants might have succumbed to their unaccustomed surroundings, or failed in the act of reproduction, there had been a few more sturdy ones who had successfully resisted the unfavorable action of their new environment, and produced children as favorably constructed as themselves. By the successive increase of these generations of properly adapted individuals, the character of the people as a whole was modified and the race firmly established.

The reproductive power in immigrants might be either greatly reduced, or it might be qualitatively affected; so that they begot children of a more delicate constitution than themselves. If the latter was the case, the race was

likely to deteriorate through several generations, unless some improvement resulted from intermarriage with more robust people.

In the city of Brooklyn, during the year 1889, there were 2,055 deaths from phthisis; of which 1,193 were in persons born in the United States, and 859 in foreigners. Unfortunately, the method of registration did not render it possible to classify the foreigners according to their respective nationalities; but the nativities of their parents were given, and in order to ascertain the number of those born in the United States whose parents were immigrants, he had deducted the whole number of foreign-born from the whole number of those whose parents were foreign-born. The death-rate from phthisis in this class was very high, viz., thirty-seven per cent. of the whole number.

What Are the Conditions which Predispose to Tubercular Consumption?—Dr. Albert L. Loomis said it was very difficult to fairly discuss a statistical paper like that of Dr. Westbrook, because so much depended upon the sources from which the statistics were derived, and upon how completely all vitiating circumstances had been eliminated. This also made the conclusions which may have been reached from statistics very uncertain. Dr. Westbrook's statistics, however, had no doubt been collected with great care; and they proved simply that under unhygienic conditions the death-rate from phthisis was higher than under good hygienic conditions. They went a little further, also, and showed that the descendants of certain races offered greater power of resistance to tubercular disease than those of others. His statement that the mortality was higher in the third and fourth generations of those descended from Irish immigrants, than in those who were born in Ireland and came to this country, would not astonish those who were familiar with the mode of life of such individuals, the conditions surrounding which are a fruitful source of great mortality, not only from phthisis but from every prevailing disease. He believed, however, that with some other races the case was different. Among the Scotch, for instance, he thought it would be found that there was no greater mortality in the succeeding generations than in the original stock. It was always a considerable risk for anyone not very strong to go into a new climate and get acclimatized to it.

It seemed to him that this whole discussion must hinge upon the question, What are the conditions which predispose an individual to pulmonary phthisis? He thought it safe to assume that there was always a period of general decline which precedes bacillary infection. If we believed that phthisis is due to the tubercle bacillus, we would expect it to be found wherever it should find its sustenance and have a chance to grow and multiply. Consequently, in large cities one must necessarily be more exposed to the risk of infection than in the country. In cities there was a better soil for the development and activity of the bacillus, and hence there would naturally be a greater death-rate from phthisis than in the country. In the former all the conditions favored this—bad ventilation, bad diet, improper modes of life, etc. Whatever impaired vitality favored the lodgement and development of the bacillus, and would be a cause for the greater prevalence and mortality of phthisis. If there was any soil favorable for the tubercle bacillus, it was to be found among tenement-house children, and those reaching adult life amid the surroundings commonly met with in the tenement-house population. If we accepted the bacillary theory of phthisis, he thought it must be apparent to all that it is simply the power of resistance which gives one individual immunity from this disease and predisposes another to it.

Aside from other conditions, we know that there are certain soils on which tuberculosis would thrive. Thus, Laënnec related that for twenty years, at a certain convent located in a clay cut, every nun died of phthisis. It might have been that the entire building was filled with tubercle bacilli; but, at all events it certainly seemed that the location of the institution had something to do with the remarkable prevalence and mortality of the disease. All such papers as that presented this evening, he believed, would help us to solve the difficulties met with in connection with the etiology of phthisis.

Effects of Acclimatization on Different Races.—Dr. Westbrook said that he thought it was true, as Dr. Loomis had said, that there was a great difference in the effects of acclimatization on different races. Different results were also noted in individuals of the same race who migrated to different climates. Thus, among those who went to tropical countries, it was found that the climate had a marked effect in diminishing fecundity; while among those who went to an inclement climate, such as was met with along the northeastern coast of the United States, the health of the individuals became impaired and their descendants were not robust.

As Dr. Loomis had remarked, children in the tenement-houses of cities had a bad start from the first, and the other unfavorable conditions to which he referred continued to act during the remainder of their lives. He thought, however, that even among the better class of Irish the same deterioration of health would be found to exist to a very considerable extent; and it had occurred to him that the change of temperature, the greater fluctuations of temperature than those to which they had been accustomed in their former home, and the rapid changes from moisture to dryness, and *vice versâ*, must have a very deteriorating effect. It might be stated, also, as a general fact, that the accommodation of the body to these changes, involving prompt readjustments to meet the sudden changes in humidity, as well as many other circumstances incident to the different climate and mode of life, all involved the expenditure of a considerable amount of vital energy. A further cause of ill health arose from the necessity of digesting an entirely different diet from that to which they had been accustomed. Moreover, it was a fact that the men, at least, were obliged to work much harder than they were in the old country. Finally, he believed that the prolonged deterioration in the health of their descendants was due, to some extent, to the circumstance that, on account of their religion, the Irish were prevented in a great measure from intermarrying with other races. If they could have some good native American stock mingled with their own, he had no doubt that it would have a very good effect in fortifying the offspring against the deteriorating influences referred to.

In regard to statistics and their uncertainty, there was unfortunately too much truth in what Dr. Loomis had said of them. The records of our boards of health were defective in many respects, and upon some points of importance afforded no information whatever. As far as the actual mortality was concerned, however, and the difference in this respect between different wards of the same city, the figures he believed were entirely reliable.

Dr. S. Baruch read a paper on "The Treatment of Typhoid Fever; a Review of Recent Discussions" (see p. 318).

Discussion.—Dr. Alfred L. Loomis said that he hardly felt prepared at the present time to discuss the treatment of typhoid by cold baths. If such baths were given for their antipyretic effect, it seemed to him that the reduction of temperature could be secured by simpler and better means than this. He was glad that Dr. Baruch was an enthusiast on this subject, and that he was willing to go as far as the law allows, and even a little further, in his advocacy of the method. When he compared the condition met with in typhoid fever to opium poisoning, however, it seemed to him that he did not properly recognize the cause of the toxæmia that was present in typhoid. The latter was believed to be due to the action of a specific infection, and such was certainly not the case in poisoning by opium. The two conditions were very different, and he did not see how they could very well be compared.

From what little experience he had had with cold bathing in typhoid, he believed that it was a powerful agent

for restoring vitality if properly employed, and that it was a powerful agent for destroying vitality if improperly used. As to its antipyretic power, there certainly could be no doubt; but when the cold bath was given without regard to its effect upon the heart, the capillary circulation, etc., it seemed to him that it was liable to do very great harm.

As regards the statistics of typhoid fever, there were very strange things. During the last two months he had treated twenty cases of the disease by means of the cold coil, without a single death; but it did not follow from this that the cold coil was the best or only treatment to be used in typhoid. If we based our opinions on statistics, he believed we were liable to error. Dr. Baruch had unquestionably placed these statistics in a most enticing way before us; and yet he felt convinced that, if he permitted himself to be guided wholly by them, he would almost surely have reason, sooner or later, to regret that he had done so. At the same time, if the opportunity occurred to him to treat a large number of typhoid cases together, he would be glad to give the method so eloquently advocated a thorough trial.

The CHAIRMAN said it was very difficult to speak intelligently about a matter in regard to which one had had no experience. Personally, he had had no real experience with the Brand method of cold bathing. The point brought out in the paper, that in the United States we have never really tried this treatment, was correct. It was a fact, he believed, that scarcely anyone here had carried out the whole treatment thoroughly. One reason for this, no doubt, was the inefficient character of most hospital nursing in the United States. The great difficulty was to get a sufficient number of nurses for the very exacting requirements of the method.

He confessed that he had had the idea that, perhaps one reason why the patients treated by strict cold bathing had done so well, was because this treatment consisted simply of three things, viz., *first*, bathing; *second*, feeding; *third*, stimulation. The fact was that in the so-called expectant plan of treatment, a very considerable amount of medicine of various kinds was almost invariably given. On the other hand, patients treated by the Brand method received no medicine whatever, and he could not but feel that this absence of drugs had something to do with the favorable results noted.

The Object of Cold Baths not to Reduce Temperature.—DR. BARUCH, in closing the discussion, said he was very glad to have been able to show that the main object of the treatment by cold baths was not to reduce temperature, but to furnish a restorative and stimulant to the nervous system. Brand, indeed, now claimed that his method was antipyretic. It was Liebermeister who was the leading spirit in proclaiming that the benefit derived from cold baths was due to their antipyretic effect, and after giving a bath he often administered forty or fifty grains of quinine for the purpose of keeping the temperature down after it had been reduced by the bath. But the result of this treatment was a mortality of eighteen per cent.

His object, then, was to show that the cold bath is not meant for the purpose of antipyresis. Antipyrine, as he had found to his cost, would bring down the temperature much more efficiently than the cold bath. As to his analogy between typhoid toxæmia and opium poisoning, he granted that the comparison might be defective in some particulars; but, at the same time, he thought the main points would hold good. In both cases we had a profound poisoning of the system, though in one case the poison acted rapidly and in the other slowly. In both the poison would become eliminated in the course of time, if we could but support the patient and prolong life until nature could accomplish this; and in both, therefore, the indication was simply to fortify the flagging powers until this could be accomplished. He did not claim that we could *cure* typhoid; but it was a self-limited disease, and what we had to do was to maintain life until it had run its course.

In regard to statistics, it was true that twenty or thirty, or even a hundred cases, were of no practical value; but if we had vast numbers of cases, the correctness of whose data was vouched for by men of the highest scientific attainments and reputation, he believed that such statistics were to be trusted.

The omission of medicine in the strict bath treatment was, perhaps, as Dr. Delafield had suggested, of great value. It seemed probable that often the medicinal treatment employed had actually damaged our patients, and in what was known as the combined treatment, in which drugs of various kinds were employed in addition to cold baths, the mortality, as had been shown in the paper, was very large.

Correspondence.

CONJUGALITIES.

To the Editor of the Medical Record.

SIR: Medical science, by an herculean labor on the part of its votaries, has educated the people in many branches relating to hygiene. The task began in an ancient time, but it has been within a comparatively recent date that the teachings have borne their ripest fruit. Memory need not fatigue itself in recalling the time when New York City was devoid of any sanitary legislation worthy of mention. Through the efforts of the medical profession the people and legislature were so enlightened that it became possible to establish a board of health based on scientific principles. Such a board is now regarded as a necessity, as an inherent part of municipal government, and a metropolitan example has spurred villages and cities, States, and the nation to unwonted activities which have promoted the general welfare.

Hygiene embraces within its scope a large number of laws, some of them relating to the body politic, and others to individual life. Many of the former can be judiciously codified, and can be enacted and enforced by legislation. Those of the latter group are so closely allied to the personalities of life that they cannot ordinarily come within the province of legislative enactment. Man, while a free agent, either to obey or to disregard them, must be so instructed that he will voluntarily yield to them submission. Hygiene is not regarded as a socialistic branch of medicine; its teachings are based on such sound foundations that they carry a conviction of their truth to the enlightened popular mind. In the wide-spread diffusion of modern medical thought the laity can almost acquire as accurate a knowledge in regard to living auspiciously as though each member of society belonged to the healing art. Academies and universities now give instruction to the youth in sanitary matters, and the gymnasium is often an adjunct of seminaries of learning and other institutions. Out-door sports are annually becoming more and more in favor, and the word outing is one of the most popularly quoted terms from the lexicographer's budget.

While there is such a widely diffused general information concerning matters relating to fresh air, exercise, sleeping, eating, drinking, clothing, bathing, etc., there is a deplorable amount of ignorance prevalent in regard to others which are of vital importance both to the individual and the race. How faulty is the education of youth in regard to the uses and abuses of the genital organs! Parents naturally shrink from talking with their children on such subjects, and children, with a kindred delicacy, shrink from making inquiries which are evolved by their ripening years. Untutored in such regards, licentiousness is smuggled into the lovely young hearts of purity, corrupting budding imaginations, and at times inducing physical and mental disturbances which prove a permanent cause of disaster through life.

It is a holy study, worthy of the medical profession, to decide how to counsel parents in regard to judiciously and chastely imparting instruction to the rising generations,

on a topic concerning which there must always be a modest, yes, a sacred reticence.

Time does not permit of a halt to consider this very important subject, for another theme is pressing for consideration, relating to matrimony, and the healthful perpetuity of the human race. No bashful tongue-tie need embarrass physicians in enlightening the world regarding certain conditions which are absolutely essential to make the closest relationship of life a blessing to the individual, to the family, and to mankind. It would seem as if the world had had ample opportunities of learning how to wed wisely, but it is too evident that it is not only desirable but essential that some sound hygienic principles regarding the topic should be more fully and distinctly enunciated if the human family is to improve the quality of its stock.

In a beautiful form of church service relating to the solemnization of matrimony occur these words: it "is not by any to be entered into unadvisedly or lightly; but reverently, discreetly, advisedly, soberly, and in the fear of God." Suppose, for an instant, that the mass of mankind married "reverently, discreetly, advisedly, soberly, and in the fear of God." and if those who had no fear of God in their souls, should marry "discreetly, advisedly, soberly," what an evolution from the present condition of man would occur, both mentally and physically, and what a new, happier, and nobler type of manhood would be established.

In the same service from which I have quoted also occur these words: "If any man can show just cause why they may not lawfully be joined together, let him now speak, or else hereafter forever hold his peace." Suppose that a physician should rise from the group of assembled guests and resent the union, saying that it is contrary to the laws of nature that this man and this woman be wedded. According to the circumstances of the case, he could in one instance object that the perils of maternity could not be borne, in another that the offspring of such union would prove puny and futile, and in others predict descendants who would perpetuate inherited taints of intemperance, insanity, scrofula, syphilis, cancer, and allied disorders. In other words, to object to the union by reason of the misery it would entail on the contracting parties, and also upon unborn ages.

Such an interruption to a marriage rite would excite as great a consternation as that experienced by Prince Henry, the Norman prelates, and a multitude of clergy and people at the burial service of William the Conqueror, when a bishop's over-eulogy of the deceased met with public resentment on the part of a daring auditor in the church of St. Stephen. Physicians to-day can find as good cause for interrupting a number of marriage ceremonies as Asceline Fitz Arthur had for interrupting the funeral services of a king.

Such methods of thwarting hygienically inappropriate unions would very properly be met with indignation; but, fortunately, there is a righteous course of making impossible the possibility of such ungracious discourtesies. If the people are thoroughly instructed in the benign laws of hygiene, before an initial step is taken looking to a marital alliance, and if they can be made to profit therefrom, then the time will arrive when the present hobbledehoyical human race will more nearly approach a normal type of existence. Civilization, lopping off its lethal tendencies, will develop a manhood possessed of length of days and conspicuous for its mental and physical vigor, and civilization, thus healthfully growing, will solve the social questions which now seem so enigmatical. It is not to be supposed that hygiene can formulate its laws into groups of decalogues and "eikosilogues," and thus single-handed elevate mankind; morality and science must combine in sounding their respective glad tidings.

"Nature abhors a vacuum," and is so generally conservative that it often happens that marriages taking place under apparently most unpromising circumstances, result in families more sturdy than human prophecy could have anticipated. As no such merciful and undeserved beneficence can be foreseen, people in mating cannot rely upon miraculous interpositions to avert the miseries known to be ordinarily incident to abnormal unions. Life under the most favorable initial conditions is liable to its future harsh and unexpected vicissitudes, and it must be admitted that apparently robust parents will sometimes beget and will bear feeble children. Such fortuitous occurrences render it all the more foolhardy to take voluntary chances against conditions which, in the ordinary course of events, generally prove disastrous. It is more illicit, indeed, than to be engaged in any lottery illegalized by human enactment.

Special attention is now being paid to the choice raising of poultry and cattle, and at the annual dog-shows both the young and the old exhibitors of both sexes boast of the pure breeds of their canines and trace their genealogical orders. If such attention is paid to the rearing of the inferior animals, of how much more importance is it to maintain a pure human lineage! From an early period of time the topic under consideration has been a subject of study, but the people have recklessly progressed unmindful of their instruction, and the world teems to-day with woe-begone inhabitants. The human family is a rather forlorn spectacle of mental and physical disability, if compared with a high type within its possibility.

The benevolent are endeavoring to ameliorate the condition of those who reside in slums. Among a large proportion of the well-to-do classes of society the earthly houses of their tabernacles are tenanted by corrupt taints. Hereditary and thieving vitiations of a variety of kinds find lurking-places and haunts in the bodies of both the rich and the poor, robbing mankind of happiness, and in large measure preventing healthful development, ripe culture, true morality, and a normal propagation of the race. The Lacedæmonians thought so much of maintaining their regal blood that they fined their king, Archidamus, for marrying a diminutive woman, for they said, "She will bring us a race of kinglets instead of kings."

Medical science is often ridiculed for its uncertainty and inefficiency, but the science is not deserving of contempt and censure. Physicians frequently find parturient women almost incapable of bearing either easy or severe travails, from causes partly inherited and partly attributable to their former hygienically irregular modes of life. A number of the neuroses and disorders of the maternal state are not such as necessarily belong to the penalty, "in sorrow thou shalt bring forth children." Many of the diseases of both single and married women are essentially preventable, and are as illegitimate belongings as though they were bastards. Noble as it is in science to furnish a group of experts to grapple with such maladies, it is nevertheless a disgrace to the century that there is a necessity for any such class of specialists. Lycurgus, on being asked why he ordered out-door athletic exercises for the maidens, replied: "To the end that the fruit they conceive may take deep root, grow strong, and spread itself in stout and healthy bodies; and withal that they may be more able to undergo the pains of child-bearing; and, lastly, if necessity should require, that they fight in defence of their children and country."

Young men, either with or without hereditary indispositions, by recklessness of living often impair the foundations of their future lives. Many, without being profligate, in many ways undermine their vitality. Thus, it is that the moral as well as the immoral are sometimes almost alike unworthy to assume the paternal state.

Physicians are constantly summoned to attend puny infants, who by most assiduous care may possibly be nursed into their teens of months, with then the slightest probability of reaching their teens in years, if smitten with any serious disorder. It would be an unpardonable offence if the medical attendant should say to the parents of such children: "Your early wild-oatism is now becomingly rewarded by these feeble and liliputian descendants."

From time immemorial the world has been seeking for an *elixir of life*. If we possessed such an elixir to-day, its use would not be confined to the *roués* of creation or to the octogenarial period of life. The supply would have to be well-nigh inexhaustible, in order to employ it in the early periods of infancy, among children born in unnatural wedlocks. Horrible to relate, in occasional instances infants are born who are dotaged and diseased, and appearing as if their brief uterine life had been spent on a Bacchanalian debauch. In the more ordinary course of events, how often does it happen that a mother has little occasion "for joy that a man is born into the world!"

The term matrimony is derived from the Latin word *matrimonium*, signifying wedlock; which in turn is derived from the word *mater*, or mother. Certainly a hallowed meaning is attached to the root of the word. The final syllables, viz., mony, closely resemble the word money, but these syllables in the word matrimony have no possible pecuniary significance. It must be acknowledged, however, that moneyed and social interests often unrighteously influence conjugal affiliations, and untold miseries are thus often entailed upon mankind.

The word mother is the holiest word which can be uttered by man in relation to human affairs. We cannot help honoring that old tribe who, being unable to comprehend the omnipresence of a Superior Being, held as a tenet that "as God could not be everywhere, he invented mothers." What a crystallized essence of pure and holy thought animated such a people. Provident foresight in regard to assuming the expenses of married life is indispensable to insure future happiness, but nuptial gyves, assumed essentially for pecuniary and social reasons, are ordinarily shackles of torment. Such is the observation of physicians, who by reason of their calling are so situated as to be able to note the secrets of domestic life, while holding them in sacred confidence.

These latter thoughts, however, are entirely tangential to the topic under consideration. The public look to special teachers for the enunciations of the principles of morality, and do not necessarily expect discourses and epistles from medical men which are distinctly ethical in their nature. It is, however, legitimately within the domain of the science of medicine to instruct the world on certain hygienic subjects, relating to wedlock, which are very largely overlooked by those entering the marital state.

Such wholesome instruction is now being widely imparted in relation to personal hygiene, is it not also a dictate of humanity to more urgently impress upon the minds of the people, as an important truth, that when wedding, companions should be chosen who have health of mind and body, and who are exempt from pernicious hereditary taints? As attachments leading to matrimony are often formed early in life, it essentially devolves upon parents, if they affectionately regard the true welfare of their children, to educate them so beneficently that the youths in choosing partners shall select and shall wed wisely. If to the attention now being given to securing mental and physical vigor there be added an equal attention in regard to the selection of life-mates, what grand results would accrue to the health and happiness of mankind! How much less would there be seen in the world

> "Of ghastly spasm, or racking torture, qualms
> Of heart-sick agony, all feverous kinds,
> Convulsions, epilepsies, fierce catarrhs,
> Intestine stone and ulcer, colic pangs,
> Demoniac phrenzy, moping melancholy,
> And moon-struck madness, pining atrophy,
> Marasmus, and wide-wasting pestilence,
> Dropsies, and asthmas, and joint-racking rheums."

Some marital unions are so uncanny that it was iniquitous in the parties who performed the marriage ceremonies. The clergy sometimes decline or hesitate to render funeral rites over the dead; a superlative conscientiousness should certainly prevail in regard to tying a nuptial knot. If the antecedents of contracting parties are not known, or if known are unpropitious, there is a necessity for inquiry, or for a cautious and judicious course of action on the part of the clergy. A clergyman may often be placed in a most delicate position in reference to deciding what is the path of duty in relation to such cases, but every community expects its clergy to act with a feeling of personal responsibility concerning the propriety of uniting parties in wedlock. The noblest callings in life, viz., divinity and medicine, can be more closely allied by a co-operation in teaching the world how to wed properly. It is a difficult task, but each profession has its holy purpose and does not shrink from arduous work in combating human errors.

Hygiene, in promoting the health and happiness of mankind, favors matrimony. It teaches how the robust can retain strength of mind and body, how the feeble can acquire vigor, and how those who are wedding can do so under the most auspicious circumstances.

People need not possess a morbid fear, in regard to wedding hygienically and propitiously. There are here, as in other communities, those of both sexes who are pure in heart and sufficiently sound in mind and body, who are befittingly adapted to become brides and grooms. Singular to say, many of those fitted either to woo or to be wooed fancy and select lives of celibacy, while others, disqualified for spousal rites, form matrimonial alliances and plunge into a maëlstrom of misery.

Lord Bacon very epigrammatically said: "Certainly the best works and of greatest merit for the public have proceeded from the unmarried or childless men, who both in affection and means have married and endowed the public." William Farr, M.D., F.R.S., in addressing the British National Association for the Promotion of Social Science, remarked: "In every society large numbers will not, and large numbers should not marry. They have wide fields of life before them, and public works, devotion, noble foundations, friendly love, will enable them to achieve those triumphs which Bacon has taught us to expect at their hands."

Let the medical profession, while instructing the people in regard to the general sanitary laws which promote the public and private welfare, raise its voice, in a becoming manner, regarding the hygienic rules which should govern those proposing to enter the conjugal state. Let the medical profession of to-day manfully perform its high office, and, in passing from the scene of action, with the waning century, leave as a benediction to mankind of the twentieth century the words which Milton placed in the mouth of the Archangel Michael, in addressing Adam:

> "So may'st thou live, till, like ripe fruit, thou drop
> Into thy mother's lap; or be with ease
> Gathered, not harshly pluck'd, for death mature."

HYGIENIST.

CONCERNING A CLINICAL STUDY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the MEDICAL RECORD of February 22d Dr. H. H. Spiers relates a case under the title "A Clinical Study," and at the end thereof propounds a number of questions to be answered, I presume, by each reader to his own satisfaction. Before this can be done it would be very desirable to know something further in regard to the pathological conditions found at the autopsy.

We are told that "the left kidney, enlarged to three times its natural size, lay about two inches to the left of the umbilicus, close to the anterior wall," also, that one-third of the organ was gone. We are told nothing whatever of the nature of this enlargement, either macroscopic or microscopic; nor are we informed in regard to what was found in the place where this kidney normally ought to be.

We are also told that the liver was "twice its natural size, and indentations on its surface made by the ribs." Was this its only departure from a normal state?

It is also stated that there was "a quart of sanious

clotted blood in the abdominal cavity. . . . in connection with the colon by many openings." We are left in complete darkness as to the condition of the colon, its walls and lumen, or the location of these many openings. Was any evidence of obstruction found?

These are some of the questions which must be answered before an intelligent answer can be given to those propounded at the end of the article.

One other point I wish to touch upon. The doctor states that "in all cases of tumor of uncertain character an exploring needle is perfectly proper." This I will not attempt to gainsay, but would like to add that in the present state of our art an exploratory laparotomy is perfectly proper if puncture does not clear up the diagnosis. This is especially true when chronic intestinal obstruction of six weeks' standing is accepted as the probable diagnosis.

This procedure, executed under aseptic conditions, would not have affected the prognosis unfavorably in any great degree. Even the insufflation of air or hydrogen gas would have given valuable information in regard to the relations of the bowel and the tumor.

With our journals almost weekly giving instances of the great benefits to be derived from exploratory laparotomy in obscure conditions of the abdominal viscera, surely it is our duty to our patients to employ all possible methods of arriving at a correct diagnosis, and to let an ante-mortem rather than "a post-mortem clear up the case."

G. S. KAUMHEIMER, M.D.

MILWAUKEE, WIS., February 25, 1890.

THE CAUSE OF THE JAPANESE STOOP.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your issue of February 8th there occurs an item relative to Dr. Kidera Yasuatsu's conclusion of an inquiry into the cause of the habitual body stoop of the Japanese, which attributes it "to their excessive politeness, the bent posture being considered one of deference." This I think an error. It is due rather to their habitual use from infancy of the elevated wooden sandal, whose stilt-like effect on the body's equilibrium, makes it difficult to maintain a perfect perpendicular, and to their habit when walking of keeping the arms folded, with hands pocketed in opposite sleeves.

Yours, very sincerely,

ALBERT S. ASHMEAD,
Late Foreign Medical Director Tokio fu Hospital, Tokio, Japan.

4 KING STREET, NEW YORK.

BROMINE IN DIPHTHERIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I do not wish to blight the hopes of the various physicians who have had such successful results from the use of bromine in the treatment of diphtheria, but I do wish to assert that in bromide they have not found that long-looked for specific, and in all probability they will be disappointed in its use for the cure and prevention of this disease. My experience with it in the treatment of my first thirty cases was such that I did not hesitate to call it a specific, and spoke of it as such in our Society meetings. But I was not as successful in my next sixty cases, treated in the same manner, for thirty per cent. of them died. I observed at the same time that the mortality of the cases treated by the other physicians in our county did not vary much from those that came under my observation, although our methods of treatment varied much. I cannot recall a family in which isolation, as far as is practicable, and the generous distribution of the bromine gas prevented the disease from attacking the younger members, although it may have saved many a life by modifying the intensity of the disease. I do not wish to be looked upon as opposed to the use of bromine in diphtheria, for I am not; but I cannot feel justified in depending upon it altogether after my experience with it. As a means of prevention, I would urge that every physician constitute himself a health officer and inspector for every family that retains him. It is his duty to look over their premises at various times, and insist on such changes from a sanitary stand-point as would be conducive to good health.

JAMES H. REILLY, M.D.

RUTLAND, N. Y.

THE MEDICAL CHARITY ABUSE AGAIN.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I regret to see that you deem it necessary to speak in an apologetic tone in again advocating "hospital outpatient reform," in your issue of last week. You can do no better work for the medical men of New York than by continuing to agitate this question. Dispensary reports are now being distributed among the charitably inclined, showing "the great increase over last year in the number of patients treated." This competition for numbers is making the private practitioner's lot each year harder. The evils of the present system of treating all comers can only be fought by combination backed by money. Those who suffer most can ill afford to supply the necessary funds, though willing and anxious to do so if they knew just how to proceed. Let some physician who has grown rich in real estate or other speculation, or some wholesale druggist who has retired on the profits of supplying dispensaries with drugs, donate a sufficient sum to carry on a crusade against this ever-increasing evil. The County Medical Society, which has done so much to drive out quacks, and otherwise to incidentally benefit the profession, while conferring good upon the community at large, would probably make the best use of such a fund.

In the rooms of an institution which dispenses bounties at the rate of a dollar a month, and which is situated not a thousand doors from No. 9 West Fifteenth Street, there hang notices to the effect that the physicians are not expected to treat patients who can obtain *adequate* advice outside. I once had investigated a series of patients under treatment here, and found that a large percentage of them were able to pay at least a dollar a visit, say two, three, or four times monthly. The authorities, however, were of the opinion that this amount could not secure the services of "adequate" men—in town. If the managers of this proud charity should investigate, they would find physicians in New York City who are themselves almost objects of charity, while probably possessing the ability to give points on adequacy to many of those composing the staffs of our numerous dispensaries; men who are in need of these one- and two-dollar patients; and men who are entitled to them. Yours, truly,

CHARLES W. ALLEN, M.D.

696 MADISON AVENUE.

THE PHONOGRAPH AND GRADUATION OF SOUND FOR TESTING THE HEARING.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the MEDICAL RECORD of March 15th, p. 300, is an article entitled "A New Use for the Phonograph in Medicine." It suggests the use of the instrument and the graduation of sound for testing the hearing. In the light of that article permit me to state that before that date I had constructed and demonstrated to individual members of the profession a scale of sound to be used on the phonograph for such a purpose. I had also arranged to read a paper entitled "The Phonograph as an Acoumetre, with a Demonstration of a Scale for Testing the Hearing," before the Society of the Alumni of Charity Hospital, at its April meeting. In explanation, I would state that the scale consists of a series of sounds produced by a certain metric weight falling various distances and striking a sonorous body. These distances are so graduated

that each sound varies from the succeeding one by one-twentieth of its intensity. We can therefore express a person's hearing as $\frac{3}{20}$ or $\frac{2}{20}$, according to the number of sounds that he can hear. A full description of the scale and the method of its production will be published immediately after the meeting of the above Society. Trusting that I have not taken too much of your valuable space, I remain,

Respectfully,

C. W. Stimson, M.D.

68 West Fortieth Street.

New Instruments.

IMPROVED SPRAY-PRODUCERS.

By J. M. Hays, M.D.,

Oxford, N. C.

The Sass spray apparatus, which is now so extensively employed in the treatment of various diseased conditions of the nose and throat, has, after successive modifications, become almost perfect as regards the purposes for which it is intended. As made at present, however, the spray-producers are open to the objection that it is frequently

impossible by their use to throw the medicated spray well into the vault of the pharynx and posterior nares, particularly if the patient is easily "gagged." In such cases the soft palate is thrown against the posterior wall of the pharynx, and access to the parts above is consequently cut off.

To obviate this difficulty I fitted the "bayonet attachment" to an ordinary bulb atomizer, for use with the Sass condenser, and found that it worked satisfactorily, except that the spray current was not sufficiently under my control, and in several cases where my patients suddenly threw their heads backward the spray flew into their faces before it could be cut off. I found that a strong solution of nitrate of silver was not an acceptable cosmetic. Messrs. Tiemann & Co. have recently made, at my suggestion, a modification of the Sass spray-producers, fully represented by the accompanying cuts, which I am now using daily, and with very great satisfaction to myself and patients.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 9 to March 15, 1890.

Davis, W. B., Captain and Assistant Surgeon. The leave of absence for seven days granted by order No. 9, Fort Preble, Me., March 7, 1890, is hereby extended ten days. Par. 6, S. O. 58, Division of the Atlantic, March 12, 1890.

Ebert, Rudolph G., Captain and Assistant Surgeon, now on sick leave of absence, by direction of the Secretary of War is relieved from his present station, Fort Pembina, N. D., and will report in person to the commanding officer Angel Island, Cal., for duty at that station. Par. 1, S. O. 57, A. G. O., March 10, 1890.

Powell, Junius L., Captain and Assistant Surgeon. By direction of the Secretary of War is relieved from duty at Fort Supply, I. T., to take effect at the expiration of his present leave of absence, and will report in person to the commanding officer at Fort Randall, S. D., for duty at that post, and by letter to the commanding general Department of Dakota. Par. 8, S. O. 56, A. G. O., March 8, 1890.

Morris, Edward R., First Lieutenant and Assistant Surgeon, Fort Shaw, Mont. Granted leave of absence for one month. Par. 1, S. O. 28, Department of Dakota, March 7, 1890.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 15, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	9	5
Scarlet fever	104	20
Cerebro-spinal meningitis	4	5
Measles	169	11
Diphtheria	100	32
Small-pox	0	0
Varicella	5	0
Cholera	0	0

Sea-water and the Nutrition of Marine Animals.—Drs. Pouchet and Chabry have recently conducted some experiments of great biological interest. They have reared larval germs of sea-urchins in artificial sea-water and in sea-water deprived of all or more or less of its lime, in order to observe the influence of the composition of the water on the development of the larvæ. Normally a distinct skeleton should develop. It was found that when the larvæ were reared in sea-water deprived of about nine-tenths of its lime, not even a rudimentary skeleton was developed. A very trifling diminution in the normal amount of lime, effected by careful precipitation by chemical reagents, was found sufficient to interfere markedly with the growth of the skeleton in the larvæ, hence the medium in which some marine germs of life exist would appear to act as a nutritive agent as well as an atmosphere whence oxygen may be obtained for respiration. The influence of the chemical composition of the water in different seas probably determines many differences in the anatomy of marine animals, but Drs. Pouchet and Chabry admit that this question requires much consideration. How far the embryo in the higher terrestrial forms of life may receive nutrition direct from substances in solution in the liquor amnii, as well as through the placental circulation, is another question worth solving.—*British Medical Journal.*

General Medication in the Treatment of Skin Diseases.—General medication is frequently of more importance in the treatment of skin diseases than local measures. An example of this was lately furnished at the college clinic. A little girl was brought with eczematous crust upon the left side of the head, involving the hairy scalp, and of the size of a silver dollar. In addition to this there existed tinea tarsi. The child, aged about eight, was pale, thin, with lymphatic glands, and presented the clinical aspect of scrofula. But little was done in the way of local medication, except the removal of the crust and application of a slightly stimulating ointment. Cod-liver oil, internally, was ordered, and in three weeks the little girl had perceptibly gained flesh, the skin lesion was cured, and she looked lively. A continuance of the oil was ordered, and in the course of time there is no doubt that this patient will grow stout and hearty. In these cases, however, it is absolutely necessary to enforce a long continuance of the internal medication in order to obtain anything like a permanent result.—Dr. A. H. Ohmann-Dumesnil, in the *St. Louis Clinique*, January, 1890.

THE ARREST AND PARTIAL RESORPTION OF IMMATURE CATARACT, WITH RESTORATION OF READING-POWER.[1]

BY RICHARD KALISH, A.M., M.D.,

OPHTHALMIC SURGEON TO CHARITY HOSPITAL, NEW YORK.

INSTEAD of premising this paper by an historical sketch, which could only be a review of what has already been published on this subject and is known to you, allow me to state briefly what brought about the investigation of this exceedingly interesting subject. In an old treatise on cataract Majendie is credited with quoting Gondret as stating that, eventually, lenticular opacity will be cured by absorption, and the dangers incident to an operation avoided. Once having noticed this, it surprised me to observe how often its repetition occurred in the writings of that period; but a search of the literature failed to throw any additional light on the subject, or give any clew to a plan of treatment. Reports of cases of so-called "spontaneous absorption of cataract" were examined with the hope that some suggestions might be gained, but without success. Here let me express the opinion that, although I have never seen a case of spontaneous absorption, I feel certain from an examination of the literature that, when it is said to occur it is brought about by the employment of some local domestic remedy, derived probably from the vegetable kingdom. I would therefore ask that this be borne in mind, so that when a case comes under notice a complete, searching, and rigid investigation of the history, habits, mode of life, and the surroundings of the patient be made, and a full and accurate account be taken of everything that has been done for the eyes, even to the minutest detail. When this plan shall have been carried out in a number of cases, I do not doubt but that important information will be gained. After devoting considerable time to research, it seemed to me that the solution of the problem of the cure of cataract *without* operation would depend upon the reply to these two questions:

1. Since non-traumatic cataract depends upon an interference with, or deficient nourishment of, the lens, how can an additional supply of nutrient material be furnished to the intra-ocular structures?

2. How can a remedy possessing solvent or discutient powers be brought into relation with the lens so that it may exert its power and cause absorption or dissipation of the opacity present in the lens?

The first requisite could be gained by any means which would bring about an increased blood-supply to the inner structures of the eyeball, and the most feasible plan seemed to be properly applied manipulation. The second requirement, which may be called the therapeutical element, seemed almost impossible of solution. At this time an article by a Dr. Mercer appeared in the *British Pharmaceutical Journal*, on cineraria maritima, which is no doubt familiar to you all, as it has been republished in almost every medical journal and many of the daily papers as well. I obtained some of the juice, expressed from the fresh leaves, from Venezuela, and gave it a fair trial. It was absolutely without effect in the cases in which it was employed, and as these were private patients and intelligent people, I am positive that the remedy was faithfully tried. The publication of Dr. Mercer's letter was through the agency of the Director of the Royal Gardens at Kew, England, and the Assistant Director, Mr. D. Morris, wrote me that nothing further was known than the original letter; which statement was also made in a letter to me from Mr. J. H. Hart, the Director of the Royal Botanic Gardens at Trinidad, to whom Dr. Mercer had written for a supply of the fresh leaves. I have been unable to find any further account of the use of cineraria, although Dr. Mercer promised to make a supplementary report after further trial of the remedy. To say the least, this silence is certainly ominous. I have devoted this extent of space to cineraria because I receive letters every few days asking if I have used this remedy, and if I would advise its employment. I can only repeat that I have found no benefit to follow its use, and am fully convinced as to its utter inefficiency. The next remedy was pulsatilla, employed in various forms—fresh juice, fluid extract and tincture of the fresh herb, and the oil obtained by maceration of the compressed herb in olive-oil and in sweet oil of almonds. Briefly stated, no benefit was obtained. Electricity in its different forms next claimed my attention. I have been able to slightly improve vision for distant objects in a few cases only, so that the outline of large objects could be discerned, but no improvement in reading-power was acquired, and in the large majority of cases nothing at all was gained. Only the galvanic current seems to have any influence, and if I may be permitted to theorize, I would say in that those cataracts where a direct interference with the function of the fifth nerve can be established, possibly electricity, together with the administration to full physiological effect of strychnia and some form of phosphorus, probably as phosphorated oil, may prove beneficial. Castor-oil, which possesses solvent power in a marked degree and which is easily and largely absorbed, was tried, found ineffectual, and discarded to make place for its derivative, polysolve or solvine. This is intensely irritating to the conjunctiva, and requires so much dilution before it can be employed that only an infinitesimal quantity is contained in the solution, and its use was abandoned. Just about this time I was informed that some in Baltimore and one in Boston were *curing* cataracts without operation. No information could be obtained in reference to what was being done in Baltimore; but I found that the man in Boston had benefited, but NOT cured, several cases, and that his treatment was a profound secret which he positively refused to divulge. I continued my experimentation with other not so well-known remedies, and made a trial of the different methods of manipulation of the eyeball, and evolved a form of manipulation which, together with the instillation of a solution to be described, I have found to produce marked and lasting improvement in near and in distant vision. As a result of this plan of treatment a very brief *résumé* of the first six cases so treated will not, I trust, be out of place.

CASE I.—German, aged seventy. Treated since November, 1888, with above first-mentioned remedies; sight not so good as before treatment. Led to my office, as she cannot see street signs or house numbers. She cannot distinguish vegetables by size or color when marketing. Right eye has light perception only; left eye sees figures at ten feet, but only in some directions. She cannot read any of the letters on the Jaeger test-card. Treatment by conjoined manipulation and instillation begun January 4, 1889. On February 14th she could distinguish, with her

[1] Read before the Section on Ophthalmology and Otology of the New York Academy of Medicine, March 17, 1890.

right eye, the outline of large objects, as houses, and with the left eye read Jaeger No. 14 at eight to ten inches. There was steady improvement up to June, when the treatment was stopped. She was then able to do her housework, marketing, and coarse sewing, as darning, etc. From January until April the treatment was kept up daily, after which she did not attend regularly, as she had a bad attack of Bright's disease.

Case II.—American, aged fifty. Commencing cataract of both eyes. Had keratitis when a child. Some opacities still remain, just above pupillary margin. Uses a convex cylindrical glass. Objects have become so dim that she is about to give up her occupation of teaching music. Vision in the right eye = $\frac{2}{200}$, in the left eye = $\frac{2}{100}$; with her glasses she can see a few letters of Jaeger No. 2 at three to five inches, but her sight becomes blurred almost at once, and the letters become duplicated. No benefit from any change in glasses. Fundus cannot be seen. Treatment by conjoined manipulation and instillation begun February 26, 1889. Marked improvement after two weeks of treatment, and in the latter part of March she resumed charge of her classes. She uses the same spectacles she has had for the past fifteen years. March 1, 1890, declares her sight to be better than in many years, and is again able to sew, which she was forced to give up over two years ago. Reads the daily papers easily.

Case III.—American, aged seventy-five. Was informed by an oculist in February, 1888, that she had commencing cataract of both eyes. In March, 1889, her vision in the right eye was $\frac{2}{100}$, in the left $\frac{2}{100}$, and accepted + 1^{00} D. spherical. With + 6^{00} D. she read with the right eye Jaeger No. 10 at six to fourteen inches, and with the left eye Jaeger No. 9 at six inches, but in both cases with difficulty, and only a few lines. Treatment by conjoined instillation and manipulation from March 1st until June 30th, when treatment was stopped with the sight greatly improved. Four months later, in October, her vision was + $\frac{3}{20}$, in both eyes—it was only $\frac{2}{100}$ when she presented herself for treatment—and with her glasses can read and sew. At the beginning of the treatment there were symptoms of chronic glaucoma, with increased tension amounting to + 1. Under manipulation, as has been noted by Pagenstecher, the tension was reduced and has since remained at about — 1. On March 10th sight was as at the last note, and tension still minus.

Case IV.—American, aged eighty. Cataract, immature, of both eyes. Vision in right eye $\frac{3}{50}$. In the left eye $\frac{2}{200}$, unimproved. She can read Jaeger No. 9 at ten inches with the right eye, and at fourteen inches with the left. Treatment by conjoined instillation and manipulation commenced March 15th, and continued until June 1st. A report from her, about two weeks since, states that she reads her newspaper easily and can do ordinary sewing.

Case V.—English, aged seventy-six. One who has tried cineraria maritima, but without benefit. She can count fingers with each eye at five feet. Impossible to see the fundus. Treatment by conjoined instillation and manipulation commenced on April 17, 1889. May 1st, the vision in the right eye was $\frac{5}{200}$, and she could read Jaeger No. 13 at four inches, but only a few words; with the left eye the vision was $\frac{1.5}{200}$; she could read Jaeger No. 13 at four inches, and the letters were made much clearer by adding + 1^{00} D. cyl. axis 90°. July 1st, vision in the right eye was $\frac{1.2}{100}$, and with + 0^{50} D. spherical = $\frac{2}{200}$; in the left eye $\frac{2}{200}$ with + 1^{00} D. spherical = $\frac{2}{100}$, and she could make out a few letters of Jaeger No. 6. Fundus can now be seen through the thinned parts of the cataract, and the results of a very extensive retinitis, in both eyes, resembling albuminuric retinitis, can be distinctly made out. Examination of the urine is negative. The retina is so badly damaged that sight could not be improved to the reacquisition of reading power, even if all lenticular opacity were removed. March 1, 1890, there has been some gain in distant vision, so that the fear of not seeing approaching horses when crossing the street is overcome.

Case VI.—American, aged nineteen. Zonular cataract of both eyes, thought to have followed an illness when two years of age, which was diagnosticated as meningitis. Left eye was operated upon four year ago—iridectomy—"to either clear it all up, or render the lens entirely opaque, so that it could be extracted." The operation was entirely unsuccessful. Vision in the right eye was — $\frac{2}{50}$, unimproved by glasses. Under cocaine dilatation the clear ring at the periphery of the lens is distinctly seen, and with the ophthalmoscope the existence of hypermetropia determined. She cannot read except by doubling the fist so as to make a canal through the partly closed hand, and looking through this dark passage. Even then the words are all not clearly seen, but are supplied from the context, and words of three or more syllables are "guessed at" from seeing the first three or four letters. Unimproved by any glass. Treatment by conjoined instillation and manipulation commenced on October 4, 1889. On November 20th she read slowly, and without shading her eye, from Jaeger No. 7. There has been a steady improvement, and on February 8th with a + 4^{00} D. spherical she read for an hour from the morning paper, and for the first time in her life threaded a cambric needle. All this is done with the right eye. The left, which had been operated upon, has improved for distant objects so much that she can distinguish by the attire a man from a woman at six to eight feet distant. *In every one of these cases there is a marked thinning of the lenticular opacity, easily discernible by the ophthalmoscope and by oblique illumination.*

My method of conjoined instillation and manipulation consists in the instillation of a mixture of equal parts of glycerine and a one per cent. solution of boric acid in rose-water. If this cause too much irritation, that is, if it last longer than five to twenty seconds, I reduce the proportion of glycerine; whereas if no irritation be caused I increase the glycerine up to double the quantity of the rose-water solution. In only one case was it possible to employ more than three instillations at a single treatment. After the first, each successive instillation, as a rule, causes more smarting. Conjoined with this instillation I employ a form of manipulation, *not message*, conducted as follows. The patient is seated in a chair with a back high enough to support the head; two drops of the solution above mentioned are instilled into each eye, and the operator, standing or sitting behind the patient, places both hands over the closed eyes, so that the tip of each middle finger rests upon the eyeball at its nasal side, the index and ring finger falling into place beside the middle finger. With slight pressure upon the eyeball the three fingers are drawn outward over the eye to the temporal side. This procedure is repeated twenty to thirty times a minute, the stroking being in one direction only, and continued for ten minutes, when a second instillation of two drops into both eyes should be made, manipulation carried on as before for ten minutes, then a third instillation, followed by manipulation for ten minutes. This is not fatiguing to the operator, provided the head of the patient be so placed that the arms of the operator may rest upon the top of the chair. This treatment is to be continued daily for a week, and then the interval between the instillations lengthened to fifteen minutes, making the treatment three-quarters of an hour in duration. After the treatment the sticky solution is wiped from the face by cloths wrung out of hot water, producing the additional effect of cooling the lids by its evaporation. Should the heat of the lids persist, the patient should remain until the lids become cool. Without going into details which cannot be of interest, I can state that I employed manipulation alone, but without improvement. This applies also to instillation of various remedies. Separately each was inefficient, conjoined they were followed by great and lasting benefit. The first noticeable effect is the marked softening of the eyeball. I would here state that in only

one of these six cases did the tension seem normal; in the other cases there was an appreciable hardening not amounting to +1, but still decidedly appreciable, a condition I have found present in by far the larger number of cases subsequently tested, both in private and public practice. In point of fact, I can say that in my experience a cataractous eye with normal or slightly diminished tension is the rare exception.

This is something I do not remember to have seen anywhere stated. On theoretical grounds the reduction of tension caused by this form of manipulation, together with the stimulation which the stroking should bring about, should quicken the circulation and cause an increased blood-supply, thus furnishing additional nutriment to the eye. Incidentally, I would suggest this form of manipulation in the treatment of chronic glaucoma, with the expectation of getting as good a result as was obtained in Case III. above mentioned. For the first few days the patients complain of tenderness of the eyeball, coming on immediately after the treatment and remaining for one or two hours; but after the expiration of about a week this tenderness ceases. There is also considerable conjunctival injection for a varying length of time after each treatment, but neither of these occurrences seems to cause more than a slight and passing discomfort. The treatment should be continued for three or four months. I have treated but a single case for a longer period than four months, and in this case, early in the second week of the fifth month, it seemed to me that the sight was beginning to deteriorate, and as the patient had reacquired the power of reading I concluded to let well enough alone and stopped the treatment. Until further experimentation shall modify my opinion, I would not advise the continuance of this treatment for a longer time than fourteen to seventeen weeks. The eyes should be examined every two weeks and an accurate record of the result, together with a diagram of the lens, should be recorded for purposes of comparison, and in order to know how much improvement is taking place and when the treatment should be stopped. This treatment should not be entrusted to an unskilled person, but should be carried on under the guidance and observation of an oculist; a general practitioner is not competent to oversee it. In one of my cases, after careful instruction the attendant became negligent, varying pressure was exerted, the manipulation done in an irregular manner, and the sight was becoming more indistinct. Under my own manipulation sight gradually improved and reading-power was restored. I now permit nothing to be done except under my personal supervision. This plan of treatment sounds simple enough, and its application no difficult matter; but in the hands of an inexperienced and irresponsible operator cannot but be fraught with great danger to the integrity of the delicately organized visual apparatus. Ill-regulated or too deep pressure is likely to bring on just what we wish to avoid, the ripening of the cataract, even if it stops there and does not seriously damage the eye itself. I would, therefore, give this earnest and timely caution to anyone employing this treatment, to attend to the manipulation personally, or to have it conducted under the watchful eye of an experienced oculist, otherwise certain failure will terminate the effort.

In addition to the above six cases I have treated ten more, but do not report them, because some of them are still under treatment, and others have so recently been treated that I prefer to wait a little longer in order to test their permanency. I can say, however, that these cases seem to have been improved even in a greater degree than those first quoted. A future report will give the results obtained in these cases.

The conclusions arrived at are: 1. Cases of immature uncomplicated cataract can be permanently benefited by my method of conjoined instillation and manipulation. 2. The reading-power can be restored. 3. The treatment must be applied daily, Sundays excepted, for two or three months, and at the first notice of lack of benefit or diminution of sight, treatment must be stopped. 4. The treatment must be under the supervision of an oculist. Finally, the delay in reporting this method of treatment is because I attempted to do what other experimenters aimed at; that is, to bring about the absorption of all of the lenticular opacity, and because I thought that, with new remedies, it might be possible to shorten the time required for this treatment. I have tried a great many remedies, and combinations of remedies, to particularize which would be a waste of time, but have returned to the solution above given as bringing about the best results.

Every patient I have treated has expressed entire satisfaction with the result obtained, declaring the treatment to be a great boon, as it seemed impossible to wait patiently with darkness stealing over the sight, becoming more and more helpless, dependent, perhaps for years, until blindness shut them in. This feeling is graphically expressed by one of my patients, who said: "I am going home now, able to read and sew, and feeling, oh, so many years younger than when I first met you; for I feared that your opinion would be but the reiteration of what I had before been told, and which amounted to this: 'That I must wait until I became blind, then submit to an operation, and if I were one of the fortunate ninety or ninety-two, all would be well;' but the fear that I might be one of the eight or ten failures filled my soul with terror and my heart with anguish. This is past now, and I trust that the horror by day and terror by night which I endured for several months will never again be part of human suffering."

THE TRUE HOMOLOGY OF THE MESAL PORTION OF THE HEMISPHERIC VESICLE IN THE PSAUROPSIDA.

By N. E. BRILL, M.A., M.D.,
NEW YORK.

In no branch of morphology has the damaging influence of starting with higher forms as the type, instead of with the lower, been so banefully practised as in the anatomy of the cerebral vesicle. In the brain of the higher mammalia the preponderance of the cerebrum is so great that the morphological parity or equality of other, and even more primordial, brain segments becomes, superficially speaking, obliterated. This is not the only thing, but those parts of the cerebral vesicles, which most nearly maintain the primitive ideal relations, become crowded out, so to speak, by the luxuriant and redundant development of the gyri of the convexity, and by the subcortical nerve-tracts and centres connected therewith. Furthermore, it so happens that those parts of the cerebrum which comparative anatomy must regard as secondary hypertrophies are of a far higher physiological importance, and consequently of greatest interest to the physician, surgeon, and psychologist.

Among the structures whose physiological rôle is still *sub judice*, and whose relative development is considerably reduced in the higher mammalian brain, is the *cornu Ammonis*, together with its terminal expansion, the *pes hippocampi*. If, in the following comparisons, we were to take the position and the relations of these parts as found in the human brain as objects of comparison with what I regard as their homologues in the reptilian brain, confusion must inevitably result, and for the following reason: The inferior or temporal horn of the lateral ventricle (paracœle of Wilder) in the human brain has attained its position by means of a revolution which results in a complete reversion of the typical position. A marsupial, a rodent, or a bat, furnishes us with a better standard. In these animals it may be seen that the mesal (spurious)[1] edge of the hemisphere is involuted in the characteristic sigmoid curve. If, however, we make transverse sections of the brain of such animals far

[1] Inasmuch as the hemispheric wall is continued by an epithelium, the word edge is to be understood in a qualifying sense, and to refer to the edge of the nervous wall only which here ends.

enough backward, near what is conventionally called the occipital part, this S shape is not so well marked, but becomes represented by an undulating line, as may be seen very well represented by Duval's plates, as well as in the specimens which I have prepared. A marked feature of such sections is the remarkable development of a gray streak, deeply stained, linear on cross-section, and which was resolved by Kupffer into a large number of small, closely crowded, angular nerve-elements; his *stratum corporum nervorum arctorum.*

In all sections of the brain of the highest lizards, such as the iguana and the anolis, in the crocodilia, also in the alligator and in all of the chelonia, if carefully stained by the old carmine method (which was too hastily abandoned for more brilliant but less reliable dyes), not only can this stratum be identified in its primitive and characteristic situation on the mesal wall of the hemisphere, but, in one form at least—the iguana—as in the lower mammalia, it shows undulations which strikingly remind one of the similar undulations in the rodentia. This histological correspondence exceeds the point of analogy, for they are almost identically similar in both cases. The point to which I wish to recur later is, that, relatively speaking, it is the best differentiated cortical area in the iguana's brain.

The view thus far detailed had been announced by Spitzka in "Notes on the Brain of the Iguana."[1] Unfortunately, the observation was published in such an obscure journal that it does not appear to have reached many American, or any European, morphologists. Consequently, one of the most progressive of the latter,[2] struck by the high development of the cortical elements of the area in question, and correctly surmising an analogy with the cornu Ammonis of the mammalia, fell into the error of identifying it with the entire cornu Ammonis. The difference between the older and forgotten interpretation—which, I believe, I can sustain by better specimens and more numerous details than were at the disposal of the former, and the latter, Edinger's view—may be thus epitomized:

1. The subiculum, or S-shaped part of the cornu Ammonis, which is the major part of the cornu Ammonis in higher animals, is composed of cortical elements corresponding to the typical pyramids in shape, and which form a layer directly continuous with the corresponding layer of the gyri of the convexity. The stratum of the closely crowded elements (the *stratum nervorum corporum arctorum*), which is the basis of this discussion, is not continuous therewith, but there is a distinct hiatus or break between the two; this same break is unmistakable in the iguana.

2. The contrast between the closely crowded elements of the iguana and the typical cortical layer separated from it by the above-mentioned break, is of a corresponding character to that which exists between the elements of the subiculum and those of the *fascia dentata* in man.

3. The peculiar undulations of the closely crowded layer found in the caudal part of the hemispherical vesicle, corresponds, first, to those already referred to as pictured by Duval in the rodentia; secondly, to the almost identically similar undulations of the temporal extension and expansion of the *fascia dentata* which follows the anfractuosities of the *pes leonis* (Spitzka), as the *pes hippocampi* ought to be called.[3] So far does this resemblance extend that, just as in the human brain, the anfractuosities are sometimes struck by the knife so as to exhibit a complete circle.

Having thus established by these fundamental requirements, viz., by histological correspondence, by topographical harmony, and by its intrinsic relations as manifested in the break, that the deeply stained streak found to be linear by Edinger, but undulated in the one which I am able to add,[4] is not, as Edinger supposed, the entire cornu Ammonis, but only the homologue of the *fascia dentata*, we are, on looking at it as a whole, struck by the following facts:

1. That the *fascia dentata* is the earliest stratum in the *psauropsida.*

2. That it includes between a third and a half of the cortical superficies as far as the latter is not glued to the striatum.

3. If the above view be accepted as correct, that this is the *fascia dentata*, then nearly the entire remainder of the thin-walled part of the cerebrum must be equivalent to the subiculum of the cornu Ammonis.

4. The entire ammonic structure, if we may thus summarize and designate the above features, extends cephalad so far as to actually merge into the histologically similar cortical layer of the occipital lobe.

To those who are accustomed to associate physiological and structural facts, the reflection will seem very natural that, in a cerebrum of primitive status, the primary relation to the olfactory lobe should be expressed in the single specialization of only one cortical area, which, disputable as its rôle in the higher mammalia may be from a physiological point of view, we know kept step in comparative development with the olfactory lobes. Zuckerkandel, in an able *résumé* of the relations of these two structures, has shown that a most complete parallelism exists between the development of the ring-shaped lobe and the olfactory. In the light of the interpretation which the case of the iguana permits us to make, it becomes indisputably settled that the entire free portion of the cerebral vesicle, in reptiles, is to be regarded as the homologue of the ring-shaped lobe. The component elements of what in higher animals is crowded to the concealed mesal aspect, and, in the highest forms, carried around in embryonic revolution to the extreme temporomesal region, are therefore the only ones fairly represented in the reptilian brain. The area, within which the highest potential of growth is to be sought for, corresponds to the function between the thin-walled and the adherent or striatal part of the cerebral vesicle.

It was the discovery of a commissure uniting the two peculiar elevations of molecular nerve-matter which Edinger, rather conventionally, I apprehend, designates as the fornix, and which is situated at the ventral end of the closely crowded layer, causing a projection laterad into the ventricular lumen, which induced Spitzka to claim for the psauropsida a callosum. A careful study of the uninterrupted series of sections I have obtained is necessary to determine to what part of the mammalian callosum this commissure is really homologous. The assertions of later authors, who have with singular unanimity neglected to acknowledge, perhaps inadvertently, the priority of the above discovery, are not at all clear, nor do they all of them harmonize. This question, as well as the interesting one, which is far from solution by morphologists, as to what the so-called commissure of the fornix really is, I must refrain from pronouncing a final opinion upon. Before leaving this commissure, I wish to call attention to a cavity surrounded by a condensation of nerve-tissue, and situated ventrad to this structure, which seems to have the character of a ventricle, whether spurious or real, I have not as yet determined.

Cerebral anatomy is full of instances of effete and reliquary structures. The highest brain contains within itself tracts and other features which persist, in obedience to the same law which maintains a relic of the chorda dorsalis in the centre of the ligamentum suspensorium

[1] Journal of Nervous and Mental Diseases, 1880, also Science, 1880.
[2] Edinger.
[3] There is no more resemblance of this structure to a hippocampus than it resembles a Cheshire cheese. Thus speaks one of the characters in Albert Smith's novel, "Christopher Tadpole;" and the comparison is certainly an apt one. This expansion, to which the term hippocampus has been applied, resembles in its undulations (usually three) the walking-pads of a carnivore, and especially that of the lion—hence pes leonis.

[4] My series includes, in addition to the iguana, the boa-constrictor, the embryo of the sand-viper, the shelltopuzik, the green turtle, the chelhydra, the nannemys, the anolis, and the alligator. Edinger's list includes the anguis fragilis, European emis, European lizard. Some of the figures given by Osborn, of Princeton College, show confirmatory features in other forms

dentis epistrophii, and a cæcal appendix in the intestinal tract.

When Tarinus, in his "Adversariæ Anatomicæ," settled the position and external shape of that small, dentated, grayish rim which bears his name, could he have dreamed that, from a morphological point of view, it was more venerable than that complicated convoluted expanse which has driven it from its original position, as the earliest differentiated cerebral cortical structure?

RÉSUMÉ OF REPORTS ON THE ETIOLOGY OF INFLUENZA.[1]

By CHARLES N. DOWD, M.D.,

NEW YORK.

THE recent advances in methods of study and in our knowledge of the cause of disease have been so great that we turn with much interest to the reports of those who have tried to find the cause of influenza.

There has been so much material to study that many pathologists and bacteriologists have been able to make extended investigations. The solid tissues, the blood, and the various secretions and exudations have been studied; microscopical, culture, and inoculation methods have been used. The results of this labor have been great, although no single cause for the disease has been given and accepted.

I wish to present a short *résumé* of the main results so far reported, and to record the negative results of some very limited observations by myself.

Examinations of Blood.—Many observers have studied the blood of influenza patients. Klebs[2] found in fresh blood from the finger-tips masses of small, actively moving bodies, of high refractive power; these bodies are similar to those which he has seen in the blood of pernicious anæmia patients. In fluid blood taken from the heart of an influenza patient two hours after death he found oval monads 2 to 4.5 μ in length and 1 to 3 μ in breadth, the smallest forms showing quivering movements and locomotion, the larger showing light peristaltic contractions. They were stained with a five per cent. solution of methylene blue in physiological salt solution, and as the movements ceased flagellæ were evident. Most of these bodies were within the red corpuscles, often two to five in a single corpuscle.

Kollmann[3] reports having found in fresh unstained blood from the finger-tips actively moving bodies—oval, round, or rod-shaped—the larger rod-like forms occasionally showing protuberances on the ends, and so approaching dumb-bell forms. Occasionally the bodies were joined together like diplococci. A few were so small that their form could not be well made out. He does not consider these bodies to be necessarily abnormal, as he has seen similar ones in the blood of healthy persons; he thinks they correspond closely to the monads described by Klebs. He did not find the flagellate forms in the corpuscles.

Further reports on the blood are given. Klebs[2] reports plate-cultures from the blood of two patients who died from influenza. There were no bacterial growths. Weichselbaum[4] examined the blood of two influenza patients; it was taken by venesection and examined microscopically; agar plates were also made. The result was negative.

Finkler[5] aspirated blood from the spleen and found streptococci, but no other bacteria after culture.

Vaillard and Vincint[6] found streptococcus pyogenes in the blood.

Sée and Bordas[7] report negative blood examinations.

Laveran[8] reports negative blood examinations.

The writer examined blood from the finger-tips of ten influenza patients; the specimens were dried in thin layers on cover-glasses and were stained with methylene blue as in the examination for plasmodium malariæ. The results were entirely negative, nothing abnormal was found. Nine of the patients had mild symptoms, their blood was taken on the third to sixth day of the disease—usually on the third day. The tenth was confined to bed with severe constitutional symptoms, his blood was taken on the second day. I also planted the blood of two of the patients on agar plates, and kept them at the body temperature. There were no growths.

The results of these blood examinations are only suggestive. Klebs' reports have not yet been confirmed. Kollmann does not believe that the organisms which he found were pathological. The other observers found bacteria which exist in other parts of the body, or they found nothing.

Bacterial Studies of Secretions, Exudations, and Viscera.—Many bacterial studies have been made from the lungs and other viscera, from the sputum, tracheal and nasal mucus, pleuritic exudations, etc. These studies have resulted in the announcement of various bacteria as the prevailing types, different observers giving different results.

The diplococcus pneumoniæ of Fraenkel-Weichselbaum and streptococcus pyogenes were the most common forms.

In the following reports *diplococci* were the prevailing bacteria.

Prudden[9] studied six cases of pneumonia complicating influenza. In one, which was fatal, he examined the lungs, in the other five he examined the sputum. In the lung he found a pure culture of diplococcus pneumoniæ in enormous numbers. In the sputum of four cases he found diplococcus pneumoniæ in enormous numbers and many staphylococcus pyogenes aureus; in one of them there was also streptococcus pyogenes.

In the fifth sputum specimen there were very large numbers of streptococcus pyogenes and staphylococcus pyogenes aureus. There were scattering forms in all the sputum specimens.

Thus in five out of six cases of pneumonia the diplococcus pneumoniæ was the prevailing bacterium; in all cases it was identified by animal inoculation and by culture on agar plates.

Weichselbaum[4] examined the sputum of 18 patients; 15 of them simple uncomplicated influenza; 1 with a complicating broncho-pneumonia; 2 had a croupous pneumonia later. The sputum was collected on the second day after admission to the hospital. In all cases there were many bacteria, these were almost exclusively diplococci, which were nearly identical with diplococcus pneumoniæ, but showed less virulence on animal inoculation.

Only twice did he find streptococcus pyogenes and twice staphylococcus pyogenes aureus associated with them. He also found this diplococcus in the urine. In ten autopsies on cases of simple influenza, and influenza with complications, he found inflammation in the frontal sinuses and antra of Highmore nearly constant; in the most severe cases they were filled with pus. In this pus microscopical examination and culture both showed diplococcus pneumoniæ, which was especially virulent on inoculation. Once he found streptococcus pyogenes and once staphylococcus pyogenes aureus associated with the diplococcus. In three cases of otitis media and seven cases of croupous pneumonia he found diplococcus

[1] Read before the New York Pathological Society, February 26, 1890. Reports received since that time have been added.

[8] Laveran: Le Bulletin Médical, No. 8; reviewed in Deutsche Med. Wochenschrift; also Berliner Med. Wochenschrift, February 6, 1890, and February 17, 1890.

[9] Prudden: MEDICAL RECORD, February 15, 1890.

pneumoniæ; also in the pus from a leptomeningitis and abscess of the brain, and once in the intestinal contents

Levy [10] studied 18 cases with the following results:

Exudation in otitis media (usually purulent).... 7 cases.
Result: Diplococcus pneumoniæ of Fraenkel-Weichselbaum (pure culture), 6 cases.
Diplococcus pneumoniæ and staphylococcus pyogenes albus, 1 case.
There had been a discharge from the ear in the last case for several days.

Pus from chest in empyema..... 5 cases.
Result: Diplococcus pneumoniæ (pure culture) in every case.

Sero-purulent pleuritic exudation..... 1 case.
Result: Diplococcus pneumoniæ (pure culture).

Serous pleuritic exudation..... 3 cases.
Result: Diplococcus pneumoniæ (pure culture), 1 case.
Diplococcus pneumoniæ and staphylococcus pyogenes albus, 1 case.
Staphylococcus pyogenes albus pure culture, 1 case.

Material aspirated from lung in broncho-pneumoniæ. Number of cases not stated.
Result: Diplococcus pneumoniæ..... 1 case.

Lung and pleuritic exudation lobular pneumoniæ (autopsy)..... 1 case.
Result: Diplococcus pneumoniæ.

Thus in the 18 cases examined diplococcus pneumoniæ of Fraenkel-Weichselbaum was the predominant form 17 times, and staphylococcus pyogenes albus was the predominant form 1 time.

Jolles [11] reports from the sputum and urine of influenza patients in Vienna a diplococcus very similar to diplococcus pneumoniæ.

Sée and Bordas [7] examined cases of fibrinous pneumonia after influenza, number not stated in review; in all cases they found a lancet-formed diplococcus.

In these five series of observations, Prudden, Weichselbaum, and Levy announced definitely that the diplococcus pneumoniæ of Fraenkel-Weichselbaum was the form found; as to the other two, we are left somewhat in doubt.

The following reports have been made where streptococcus pyogenes was the prevailing form:

Ribbert [12] made bacterial examinations from seven fatal cases of influenza; five with pneumonia, two without it. In five cases streptococcus pyogenes was the only characteristic micro-organism. Staphylococcus pyogenes aureus was occasionally associated in moderate numbers. In one of the non-pneumonic cases he found a pure culture of streptococcus pyogenes in great numbers; in the tracheal mucus he found it associated with staphylococcus and other bacteria. A similar condition was found in one of the pneumonic cases. He examined three spleens and three kidneys, the results were negative, excepting in one spleen where he found streptococcus. In the sputum he regularly found numerous streptococci. In two of the pneumonic cases he found no micro-organisms. The pneumonococcus was not found in any case.

Finkler [6] made bacterial examinations in influenza pneumonia cases as follows: Lung, spleen, and other parts of body, *post mortem*, two cases; lung by aspiration, six cases; sputum, twelve cases; pus from otitis media complicating pneumonia, two cases.

Results.—In all pneumonic lungs streptococcus pyogenes. In one pneumonic lung a staphylococcus and a diplococcus which differed essentially from the diplococcus pneumoniæ (Fraenkel's). In two pneumonic lungs a large bacillus (not Friedlander's bacillus pneumoniæ). In the sputum he found the streptococci in all cases but two. Generally staphylococcus aureus or albus were associated, bacilli a few times; diplococci twice. In pus of otitis media, one case, a pure culture streptococcus pyogenes; one case streptococcus pyogenes and staphylococcus pyogenes albus. He also reports having found the same streptococcus in cases of bronchitis with influenza, and in the pericardium and the spleen.

Vaillard and Vincint,[9] Hôpital de Grâce, Paris, found streptococcus pyogenes in all examined cases in the blood, spleen, lungs, and pleuritic exudation; in three cases it was in pure culture; once staphylococcus pyogenes was associated; they also found streptococcus in the sputum.

Prudden [8] examined the sputum of three cases of bronchitis complicating influenza. In two there were large numbers of streptococcus pyogenes, in the third there were large numbers of diplococcus pneumoniæ, in all there were a few scattering forms.

Laveran [8] found in sputum of many cases streptococcus pyogenes very abundant.

Du Casal [13] found it constant in the sputum of fourteen cases of influenza.

We thus find six series of observations in which streptococcus pyogenes was the predominant form.

Babes,[14] in Bucharest, examined the nasal secretion, and sometimes the sputum, of nine influenza patients. He made numerous agar plates and animal inoculations, and separated the different species of bacteria with much care. In five of the cases the predominant form was a bacillus which he designates Bacterium II.; another form, which he calls Bacterium I., was found in four cases, often associated with Bacterium II. These forms he announces as new ones, and suggests that they may be a pathological element in the disease. He also found numerous other forms; he only found streptococcus pyogenes in one primary case of influenza. In secretions of patients suffering from the sequelæ of influenza he found many forms of bacteria, but announces none as predominant.

Bouchard [15] found in secondary affections three different forms—staphylococcus pyogenes aureus, pneumonococcus, and streptococcus pyogenes.

Conclusions.—If we review these results we find that in three series of observations, embracing about thirty cases, diplococcus pneumoniæ of Fraenkel-Weichselbaum was the predominant form; in six series, embracing sixty or more cases, streptococcus pyogenes was the predominant form; in four series the reports leave us somewhat in doubt about the predominant form. Both the diplococcus pneumoniæ and streptococcus pyogenes were found in the lungs, sputum, and other secretions, and in various exudations, and each was many times found in pure culture, *e.g.*, in the pus in otitis media Finkler finds pure growths of one, and Levy finds pure growths of the other. Both of these forms are found in the mouth and air-passages in health, or conditions of slight disease, and they seem ready to set up their action when inflammation provides a suitable medium for growth. The general belief is that they have not been the cause of the influenza, but that they have developed as the influenza has provided them with a suitable condition for growth, and that their development may have caused some of the complications.

Economy Down East.—A woman in Saco recovered too rapidly, and had half a bottle of medicine left of the prescription ordered by the attending physician. Having been brought up to believe that wastefulness was a sin, and the druggist refusing to refund anything on the offer to return the half bottle, she gave it to her pet dog who seemed to be ill. The dog died.

THE THERAPEUTICS OF CARDIAC DISEASE.[1]

By H. N. HEINEMAN, M.D.,

PROFESSOR OF PRACTICE OF MEDICINE IN NEW YORK POLYCLINIC.

When we speak of the therapeutics of cardiac disease, what is it that we mean? To what are our remedies addressed? What are the conditions that pathology has unfolded that are amenable to treatment?

We are concerned with the heart both in its anatomical, as well as in its physiological aspect. Next to its position and size comes the consideration of the heart-muscle; of this muscle as a vast mass making up the ventricular and auricular walls, acting through columnæ carnæ and papillæ upon tendons which control the action of valves; with these valves themselves; with the endothelial layer, the nerve distribution of the organ, its own blood-vessels, and, finally, with its relation to the circulation and circulatory fluid and some of the more important viscera, as the lungs and kidneys.

Careful examination reveals to us what changes have taken place, and clearly and sharply must we decide which are the pathological conditions to which remedial agents shall be applied; which factors first demand, and for how long, our attention; when shall consideration be given to others, and, finally, when shall we cease in our attempt to influence the heart itself, having attained the limit of scientific therapeusis.

While it is not within the province of this paper to wander strictly from the realm of therapeutics, still. I think it not amiss to group together, so as to have before us, what are now considered the important lesions of cardiac disease, and for some of which treatment may be attempted.

At the outset I would urge attention to the probable congenital condition of the heart and arteries. Abnormally small hearts, associated with imperfectly developed aorta and blood-vessels, are by no means a rare congenital condition. Similarly other and less frequently occurring congenital abnormalities are met with. In most instances, however, we meet with acquired disease. Thus we are called upon to treat either disorders of the heart-muscle, or else these associated with valvular lesions or lesions of the orifices; or with atheromatous and sclerosed arteries of the heart or of the aorta, or of the entire arterial system. Still further, with the latter combination, in which the arterial involvement is the result of extraneous local causes, as tumors pressing upon them, or constitutional degenerative changes proceeding from other viscera, as disease of the lungs or renal system. Finally, we meet the category in which the nervous control or distribution of the heart is at fault, in which the heart-muscle may remain normal, or be itself ultimately secondarily changed, hypertrophy, dilatation, and degeneration supervening sooner or later. Such are the cases of tachycardia, abnormally slow heart, intermittent and arrested heart-beat, and some of the obscure cases known as angina pectoris.

The condition of the blood has an important bearing upon the condition and progress of many cases of chronic heart disease, and the consideration of the two conditions—plethora and hydræmia—in connection with a given case, frequently furnish important data for treatment. Bollinger has well established the fact that a condition of plethora alone, maintained for some time (as is evidenced in persons, as beer drinkers, who over-eat and over-drink, and exercise comparatively little, who in consequence have a pulse of high tension), leads to hyperæmia and hypertrophy, and ultimately to dilatation and insufficiency of the cardiac muscle.

Similarly hydræmia, with its increased quantity and its involved impoverished albuminoid condition of the blood, results in degenerative changes similar to those ultimately produced by plethora.

[1] Read before the New York Academy of Medicine, February 20, 1890.

To make a brief *résumé*, then, of the various cardiac conditions we are called upon to treat, would give us:

a. Hypertrophy, concentric or eccentric, alone or in combination with dilatation.

Dilatation alone or combined with hypertrophy.

b. Hypertrophy and dilatation, or combined; together
1, with mitral disease (stenosis or insufficiency);
2, with aortic disease (stenosis or insufficiency);
3, with mitral and aortic disease in their various combinations;
4. with disease of the pulmonary artery, or else this with
a, mitral disease (stenosis and insufficiency);
b, aortic disease (stenosis and insufficiency).

If we group our cases upon an etiological basis, we have hypertrophy and dilatation, either or both, or combined with valvular disease, the result of

a, Congenital causes;
b, work or excess;
c, fright and hysteria, and other nervous causes;
d, indigestion, mal-assimilation, etc.;
e, inflammation (causes producing endo- and pericarditis, myocarditis, and interstitial myocarditis);
f, degeneration;
1, Fatty infiltration;
2, fatty, granular, waxy degeneration;
g, either inflammation or degeneration, the result of infectious diseases;
h, either sclerosed coronary arteries (thrombosis and embolism, chronic fibroid degeneration of heart-muscle, or both of these combined);
i, either obstructed circulation, and acting secondarily through changed blood state (tumors and aneurisms pressing or interfering, pulmonary diseases, as emphysema, etc., renal disease).

Contracting our eumeration of all cases still more, we have hypertrophy and dilatation, either or both, or combined with valvular disease and associated with—*a*, plethora; or, *b*, hydræmia.

It is the natural tendency of a viscus to seek to restore itself to a normal state or to adapt itself to new conditions and surroundings. Nowhere is this better illustrated than in the heart-muscle, which by a system of compensatory hypertrophy seeks to resume its normal vigor and functions.

As long as this holds good, irrespective of the nature of the lesion, little or no treatment is required at our hands. In all cases it is the insufficiency of the cardiac muscle and the resulting lack of presentation, whether evidenced by dilatation of the heart-wall, by intermittent or irregular action, or by weakened cardiac impulse, which furnish the keynote for treatment. Similarly, whatever we may be enabled to do in advance to prevent this latter change is a proper object of therapeutic endeavor.

In the attempt to tabulate all our means of combating cardiac disease, their arrangement under the headings of hygienic, dietetic, remedial, and mechanical agents, is sufficiently broad as to include all.

Some act temporarily, some permanently, some locally, others constitutionally. While a few act directly upon the heart-muscle, most act indirectly by changing blood states, or restoring altered nervous tone. Finally, it must be confessed that some act in a manner whose *rationale* is not entirely clear or satisfactory, but whose results force us to adopt the measure; while, conversely, we must deplore our failure to influence some conditions of the heart despite all our methods and multiple resources. In speaking of the treatment of cardiac disease, I need not refer to that general treatment which any case, whether of cardiac origin or not, may require, for the more perfect is the general health, the better does each individual organ perform its function. Here, as in other diseases, specific treatment directed to the heart itself may fail, when general supporting treatment will accomplish the result.

Under remedial agents we have, as most important, digitalis, strophanthus, convallaria, sparteine, and adonidin;

veratrum and aconite; ergotin and strychnia; the general tonic remedies, cod-liver oil, iron, cinchona, and the like; bromides, belladonna, hyoscyamus and its congeners; iodides; galvanization.

As temporary agents only, we have alcohol, caffein, and thein; ether, chloroform, ammonia, camphor, and musk; nitro-glycerine, nitrite of amyl, opium, counter-irritation, faradization, zinc, arsenic, phosphorus, barium salts, venesection.

The Dietetic treatment includes the regulation of the relative solid and liquid foods, and the absolute control, as to the character and quantity, of both, depending upon indications of the cardiac condition and the blood state.

The Mechanical includes massage and exercise, by walking, by climbing, by medical gymnastics, active or passive movements, or else a combination of these, and, finally,

Medicinal Baths.—These latter may likewise be aided by some form of exercise or massage.

Hygienic Remedies.—The limit of time for the evening forbids any very detailed consideration. The effect of unhealthful trades and atmospheric surroundings must be guarded against, as is forcibly illustrated in the tobacco manufacture, and in others to a less degree. Tobacco and alcohol both give rise to cardiac disturbance, and may lead directly to cardiac overaction and hypertrophy.

Dietary Treatment.—We are so long accustomed to associate certain diatheses as tending to predispose to cardiac disease, that it is a matter for surprise that the dietetic treatment has been, until recently, although spoken of in books to a slight extent, carried out in practice even less. It is not uncommon [1] to meet with cases of cardiac irregularity and more or less dilatation in which the sole cause seems to have been an insufficient and improper diet, associated with bad hygiene and overwork.

The quantity and quality of the food is, therefore, the first consideration. This will give us a circulating fluid which leaves the heart unembarrassed, and does not tend to fatty deposit, to the gouty and other diatheses.

The indiscriminate use of water during meals embarrasses digestion, and may, in cases of fatty heart, after a hearty meal, if exercise be attempted immediately, give rise to heart failure.

Oertel's indications for the dietetic treatment are clear and explicit, and are briefly summarized in the following:

1. In cases of chronic heart disease, in emaciated or slightly built persons associated with anæmia and hydræmia, and with insufficiency of cardiac muscle:

Increase the quantity of albuminoid foods, the object being to increase the muscle element, not only up to the normal state, but even to a condition of hypertrophy and hyperplasia.

Rest and fat formation on the one hand, exercise and blood and muscle formation on the other, are the things to be sought after.

2. *a*. In cases of abnormal adipose tissue with plethora, and commencing insufficiency of cardiac muscle:
   1. Increase the amount of albuminoid food.
   2. Diminish the amount of fat-making substances.
   3. No change in liquids other than is physiological.

   b. In cases of abnormal adipose tissue with hydræmia and insufficient cardiac muscle:
   1. Increase the amount of albuminoid food.
   2. Diminish the fat-making substances.
   3. Diminish the quantity of fluids.

   c. In cases of adipose deposit in old persons, with hydræmia and commencing insufficiency of cardiac muscle:
   1. Increase the albuminoids.
   2. At the outset continue the fats and carbohydrates, yes, even increase them for a time, in order to prevent the too rapid diminution of fats when this begins to take place, an occurrence characteristic of old persons when their dietary is in any way interfered with.
   3. Diminish and regulate the fluids.

As regards the relative amount of foods indicated for the adipose cases, Oertel gives:

	Albuminoids. Gm.	Fat. Gm.	Carbohyd. Gm.	Fat equiv. Gm.
Maximum	170	43	114	173
Minimum	156	22	71	127

Ebstein gives, in his treatment of the fatty diathesis:

	Albuminoids. Gm.	Fat. Gm.	Carbohyd. Gm.	Fat equiv. Gm.
Daily average	102	85	47	154

In the cases of adipose deposit more particularly associated with hydræmia, and in older persons, food must be given in small doses and often, and fluids must not be given with solid food.

By abstaining from fluids fat absorption is promoted.

Finally, when fat disappears new formation of blood and muscular tissue is called for in the body, and the fat is replaced by muscular tissue.

In these cases exercise is used not to increase the amount of albuminoid deposit so much, as to assist in the elimination of fat. This overfeeding continues only up to a certain limit with marked increase of blood and muscle formation; when, however, fat is deposited in large amounts in the body, the quantity of blood diminishes and anæmia supervenes.

That these rules cannot fix absolute limits will, I think, be readily appreciated; each case must be treated with some regard to the idiosyncrasies and peculiarities of the individual or the heart itself. Of course it is apparent to all that the promise of success from the dietetic method depends upon so many factors that disappointment is not infrequent. It is so difficult to retain the unwavering support of the patient, that herein is the element of greatest uncertainty.

Remedial Agents.—It is worthy of note, in using the cardiac stimulants, that the combination of several of them will often give better results than the use of either of them alone. Still further, by the combination unpleasant effects are often avoided.

Thus strophanthus and convallaria give better results combined. My own experience has led me to prefer tincture of strophanthus to the alkaloid strophantin.

When digitalis is combined with strophanthus, using the former in small doses, we obtain all the good results of each drug without the cumulative effect of digitalis.

Calomel at times increases the efficacy of digitalis, whether by relieving the congestion of the intestinal tract and improving the hepatic circulation is a matter of conjecture. In using temporary cardiac stimulants, the previous habitual use of tea or coffee or alcohol gives us an indication or contra-indication for the use of thein, or caffein salts, or the natural beverages. The habitual use of large quantities of coffee by the Germans has led Furbringer to adopt the use of tea or thein in his ward as a cardiac stimulant, and with markedly good results, whereas caffein had previously proven abortive. Musk, so long recommended, is looked upon with scepticism, and unjustly so; too small doses account for its inefficacy. Recent experience has taught me that by addressing myself to the drugs which act upon unstriped muscular fibre I have succeeded in decidedly improving the tone of the heart-fibre; thus, by the administration of full doses of strychnia and ergotin I have, in many cases, after previously regulating the heart's action, strengthened it beyond expectation.

In these cases nux vomica or strychnia were used in full physiological doses. I do not doubt but the combination of digitalis and quinia, long a favorite one, proves

[1] Both in the Polyclinic and at the Mount Sinai Hospital quite a number of Russian emigrants, after two or three years of labor of twelve to sixteen and eighteen hours daily, fed upon bad diet and in poor surroundings, have been met with suffering in this way.

beneficial, not only through the tonic action of the cinchona, but also in part by reason of its effect upon muscular fibre.

The subject of counter-irritation deserves a passing allusion. The cautery (either the heated glass rod, the Paquelin or galvano-cautery) applied superficially in vertical lines over the hepatic or præcordial region is a decided means of temporarily regulating the heart's action. In simple irritable heart, from reflex causes, this may be repeated with good results.

In speaking of the treatment of cardiac disease, I need not refer to that general treatment which any case, whether of cardiac origin or not, may require, for the more perfect the general health, the better does each individual organ perform its function. Here, as in other diseases, specific treatment directed to the heart itself may fail when general supporting treatment will succeed.

Historically we find Albertius and Valsalva firm in the belief that the condition of hypertrophy and dilatation in cases of chronic heart disease could be ameliorated.

Rest in bed, blood-letting, a limited diet, and an allowance of bouillon were the main features of their treatment. Laennec suggested similar regimen.

Later we find other authorities suggesting further changes. Blood-letting in all stages, save in the latest, continued to be recommended, and now rest in bed was replaced by consent to be up and about in an equable temperature. The diet was to be a moderate vegetable diet, with moderate use of beef and milk, and simple drinks in small quantities.

Wunderlich, besides seeking to prevent further changes in the heart by symptomatic treatment, sought to establish a definite relation between the capacity of the heart and the quantity of blood to be acted upon by it. Again blood-letting was recommended as a ready means to adapt the heart to the task of the quantity of work to be done, otherwise his suggestions coincided with those above given.

Stokes led in the new departure, in recommending gradual and increased exertion and exercise for cases of fatty heart, suggesting moderate mountain-climbing in Switzerland and England. Only in very old persons, with complications, was caution in adopting this recommended; in young persons it was urged. He also suggested meat diet, and abstinence in these cases from fatty foods, soups, and vegetables. Moderate indulgence in water, with wine or whiskey, unless in advanced stages, was suggested.

Unfortunately these valuable suggestions were soon lost sight of and received no recognition.

Later, Bamberger referred to the fact that exercise had been recommended for fatty heart. It is to Oertel, however, that we are particularly indebted for the more perfect development of both the mechanical as well as dietetic plans, placing these both upon a scientific basis, and by his results inducing others to follow his example, and achieve his brilliant results.

Mechanical Method.—It is a well-known fact that proper exercise of a muscle leads to its hypertrophy, even muscular fibre which has in part undergone fatty degeneration may become changed in character and the muscle assume a normal healthy aspect. Still further, in cases where advanced degeneration has taken place, some of the healthy fibres remaining may ultimately hypertrophy, and by predominating over the degenerated fibre restore action to a formerly partially useless muscle. And even more than this, the restored tissue, by subsequent cell-growth and reproduction, furnishes new fibre, and in this manner fatty degeneration, fatty infiltration, and even interstitial degenerative changes, lose their influence, and a return to a normal, or nearly normal, function is brought about.

That these changes take place in the heart-muscle is clinically demonstrable. We have all repeatedly witnessed the more or less complete compensation in the heart, as evidenced in the disappearance of the signs and symptoms of a passive and active congestion, and in an improved heart-action itself, showing that the weakened or insufficient heart-muscle had been more or less restored.

Exercise increases the functional activity of the heart, causes an increased flow of blood to it, and improves its nutrition. When the heart is weakened by any cause, this effect becomes apparent upon the slightest muscular contraction; and when the entire body is put in regular motion, as may be done by regular walking, climbing, or gymnastics, the heart tends to beat more regularly and more frequently, the contractions of the muscles send the venous blood to the heart in greater quantity, the arteries become dilated and filled, the capillaries widen, a freer circulation is established, the pulse is increased in frequency, and the intra-arterial pressure is permanently increased—the increase during and immediately after exercise being very great, gradually diminishing after the period of rest, but remaining for eight or ten hours, sometimes even twelve and twenty hours. That a general influence for good results from the general assimilative molecular changes which exercise, however moderate, favors, is evidenced from the increased flow of urine and excretion of urea. Indeed in cases of general anasarca Oertel has formulated the rule, that "if the urine contain large quantities of albumin, and the difference between fluids absorbed and excreted is more than fifty per cent., and by diminishing the fluids absorbed no improvement in the percentage excreted is gained, in such cases mechanical treatment is decidedly contra-indicated." Returning to what we have just previously alluded, it is a matter of great interest to compare the sphygmographic tracing before and after the mechanical treatment—and likewise to note the increase by the sphygmanometer of the intra-arterial pressure.

In the sphygmographic trace we note, after exercise, that the line of descent almost equals that of ascent, the recoil rise being only a fraction of that prior to the exertion. The sphygmanometer teaches us that the increase may be ordinarily as much after a fair amount of exercise as 18 to 20 mm. of Hg., this gradually diminishing to from 1 to 3 at a varying period of from eight to eighteen hours later.

Oertel claims that a well-regulated mountain climb, of very gradual ascent is the best means of applying exercise in cases of heart disease, amenable to mechanical treatment. Selecting the mountain-sides in the health-resorts of Germany and Switzerland, he has carefully fixed the limits of the exertion to which the individual is subjected to, by varying the length, duration, and steepness of the climb. It is not a climb at random anywhere and under any circumstances, but one under careful regulation, the amount of effort required and its results being carefully calculated in advance.

As it may not be a familiar fact to all, that a diseased heart, so long as its compensation remains unimpaired, will permit of indulgence in enormous physical strain without injury in many cases, the following examples will not be without interest. A case has recently come under my observation, of a lad, nineteen years old, who presented himself at the New York Polyclinic, complaining only of dyspeptic symptoms and of palpitation, who had in early youth suffered from rheumatism. Examination revealed the lesions of aortic stenosis and insufficiency, the latter a little more marked; dilatation, with well recognizable compensatory hypertrophy, was discernible, the heart beating regularly, and there being no evidence of heart-weakness or even of ill-health. Upon investigation I ascertained that for years the lad had been a member of a German turnverein, and had twice or thrice, weekly, spent several hours hard at work in the gymnasium. In this case he had labored under the control of a competent and careful inspector, with benefit to his heart. I well recall the case of a 'longshoreman, who died at the age of sixty-nine, at Roosevelt Hospital, and who from his clearly related history had carried a mitral lesion for fifty-two years.

If under favorable circumstances, then, a markedly diseased heart can bear so great a strain because this has to some extent been carefully regulated, it is not too much to presume that, knowing the good effects of exercise, if our cases are properly selected, some diseased hearts with insufficient muscle may, by some form of judiciously regulated exercise, be more or less improved. And more particularly when we remember that it is less through the direct effect upon the heart, but rather through the improvement obtained in the circulation and circulatory fluid, that our result is obtained.

A priori, stenosis of the mitral orifice is a contraindication to the mechanical treatment of cardiac disease, rather than regurgitation. The means by which the mechanical method acts aid the condition and tendency of the heart-muscle in the latter class of cases and retard it in the former.

In mitral stenosis the circulation is certain to be interfered with, irrespective of the condition of the cardiac muscle. In this condition the circulation feels the effect of the retardation most promptly, extending beyond the pulmonary circulation to the venous system; and the auricle compensates slowly, and only after some time. To introduce the mechanical treatment here would only increase the hindrance to the venous circulation, for the more quickly you seek to drive a fluid past an obstruction the more the obstruction becomes felt. Stenosis of the aorta, on the contrary, is soon followed by compensatory hypertrophy of the left ventricle, and here the mechanical method finds an application.

In insufficiency of the valves, more particularly of the left side of the heart, we have a class of cases in which nature soon follows the lesion, by a compensation in the heart-muscle itself; and because the mechanical method acts by assisting in maintaining, in restoring, or in increasing this compensation, we have in this a mode of treatment which completes what nature, if left to herself, only partially effects in many instances.

How long mechanical treatment should be continued in these cases is a very serious question. In addition to dietetic and other measures, these cases, even when the heart is acting well, should remain more or less constantly under observation; for, although compensation may be obtained, yet it is a matter of great uncertainty how long it can be maintained. It is therefore advisable either to continue the treatment in a moderate manner, or to replace more inconvenient methods by more convenient, or comfortable, or less severe ones, omitting the method entirely whenever a premonition of failing compensation is recognizable, either in the general circulation or in the heart, particularly on the right side.

In cases in which insufficiency and stenosis are combined the question of the utility of the mechanical method will depend upon the fact whether the stenosis or the insufficiency predominates, and, still more, whether the stenosis be that of the mitral orifice, in which the compensation of the auricular wall is at best unsatisfactory and uncertain. Still, if by first resorting to palliative means we can improve or control the latter, then this may be employed with subsequent benefit.

Finally, in cases of fatty degeneration or fatty infiltration, whether associated with plethora or hydræmia, the mechanical method, carefully applied, associated with dietetic means, is a powerful restorative of lost compensation. Frequently only after a persistent combination of the mechanical and dietetic treatment, by which means the nature of the heart-muscle is more or less changed, do we find that drugs will exert any influence whatever.

By exercise and diet the increased blood-supply to the heart, the dilatation of the capillaries and arteries—which involves, of course, the coronary branches as well—permits increase of nourishment to the muscular tissue, by which the above result is obtained.

As to the modes in which the mechanical method may be applied each has its votaries, who in their preference are guided largely by surroundings and ultimately by their success under these circumstances.

While Oertel's method adopts the walk, or climb, or the combination of both—so that at the health-resorts your eye meets the familiar sign on the hill-side, this is "the beginning" or "the end of Oertel's walk"—others find this crude and unsafe.

The Swedish movements medical gymnastics—the term given by Lingg to a systematized series of movements, active and passive—are preferred by some. I presume most of you are familiar with these movements, and will not delay you further in explaining them.

Massage may likewise be resorted to. Still further, some physicians carry out themselves, or intrust to a trained assistant, a series of movements which are resisted by the patient, such as are produced by bracing the hands against each other and the like, always avoiding any direct strain upon the heart or lungs, and increasing the severity of the exercise, as habit and returning vigor upon the patient's part indicate. The aim being gradually to call into play all muscles of the body—a mild wrestling match as it were—but without subsequent fatigue.

Baths.—It is now almost twenty years ago since the waters of Bad Nauheim, although used for many years, received systematic attention for their influence upon rheumatic, and the consequent cardiac, disorders. Jacob of Cudowa, and later A. Schott, deceased, resorted to these baths, and combined their use with medical gymnastics in some form, for the relief of heart disease. This good work has since been continued by the brother of A. Schott, Dr. Theodore Schott, as well as by Bode, Groedel, and others.

Bad Nauheim is situated in the valley of the Rhine, an hour's journey from Frankfort-on-the-Main, *en route* to Cassel. It has an elevation of four hundred metres, has a sandy soil, has a gradually inclined mountain-side at one extremity, and extends out into a wide plateau on the other sides. It contains a number of springs, more or less powerful, containing large admixture of alkaline salts, chlorides of calcium and soda, of sulphur, iron, and abundant free carbonic acid. The temperature at which the baths are given varies from 88° F. in some to 90° and 93° F. in others. The waters are used by being diluted with ordinary water at first, and the temperature and the duration of the bath and change in its character regulated after the age, condition, and daily indications of each case. The physician gives daily minute directions for the bath, and visits his patient at varying times after the bath to study and note the effects. The improvement in the blood state is exceedingly marked, and the nearer a given case of cardiac disease comes within the range of being influenced by improved blood conditions, the more certain is a good result to be expected.

Hand in hand with this medical gymnastics have been made use of, and when a careful dietary has been added the opportunities of securing improvement increase.

I cannot refrain from referring to a case of an infant suffering from rheumatic purpura, associated with impoverished blood state, in which all the blood-vessels of the body were at fault—hemorrhages beneath the integument, behind the orbits, into the kidneys, etc., and finally pain and stiffness in all the joints supervening, with more or less complete ankylosis of some of the joints. In this case, within a fortnight after the beginning of the baths, without internal treatment, the joints were restored, and within six weeks all evidences of hemorrhage had disappeared.

Surely where such marked results have been secured, our expectations for some amelioration in favorable cases of cardiac disease may be realized. If hydræmia and plethora can be influenced in this manner, we have a potent means of improving not only cases of insufficiency and stenosis, in which the relative dilatation and hypertrophy is dependent upon either of these conditions, but even more so in many cases of degenerated or infiltrated heart-muscle, by the improved nutrition it brings to the muscle-fibre.

I quote a case of aortic stenosis and insufficiency, with compensatory hypertrophy, in a man, sixty-eight years old, a sufferer from chronic gout.

The improved tone of the heart-muscle as the result of baths alone, could not be denied.

Similarly I quote two cases of aortic and mitral disease in two females, both married, one aged forty-five, the other fifty-seven. In the latter, although arriving with marked symptoms of failure of compensation, within six weeks the dyspnœa, œdema, and fluid in the pleural cavities disappeared, and the patient returned to her home in Boston a much-improved patient.

Ample material could be supplied by others whose experience has led them in this direction before me, but today, among the seven or eight thousand persons who have sought the benefits of Bad Nauheim during the past summer, Russia, France, Austria, Holland, England, Sweden, and America, all have furnished their quota of patients, whose numbers, I am certain, will in the future be much increased.

Dr. A. Schott has, within his own and his brother's experience, treated nearly three thousand cases of chronic cardiac disease, and his results, drawn from so considerable an experience, are worthy of our encouragement. With a commendable conservatism he has differed from Oertel in the mode of applying the mechanical method. Schott regards mountain climbing, however well regulated, as suited only to the latest resources after the heart has been materially strengthened by milder measures. Accordingly he resorts first to the dietetic method and baths, next to moderate passive or active movements, regulated so as to avoid dyspnœa and overaction of the heart, and, last of all, permitting his patient the daily resort to a moderate hill-side climb.

Nothing during the past years has given rise to more animated discussion and attention abroad than the dietetic-mechanical treatment of chronic heart disease, and I quote with pleasure these words of Leyden,[1] spoken during the past year: "I have referred to the progress of the therapeutics of heart disease in the past years, made partly by the acquisition of new medicinal remedies, but in part also by the introduction of the dietetic-gymnastic method, which in a certain sense has introduced a reform in the domain of therapeutics. Even though the controversy continue, and the results and indications have not altogether been made clear—which is not surprising, considering the complicated objects of internal therapeutics — we must, beyond cavil, confess to actual progress in this direction."

If, though, we are not yet settled in our convictions, and more experience be needed to make indications clear and results unequivocal, yet we must admit that at no time does help for the chronic cardiac invalid seem nearer at hand than now, to prolong his life and to postpone the time of failing compensation.

49 West Fifty-Seventh Street.

A Definition of "Unprofessional Conduct."—In a bill to regulate the practice of medicine, recently introduced in the Oregon Legislature, there is a clause providing for the revocation of licenses for "unprofessional conduct," which is defined in the bill as follows: First, the procuring, or aiding or abetting in procuring, a criminal abortion. Second, the employing of what are known as "cappers" or "steerers." Third, the obtaining of any fee on the assurance that a manifestly incurable disease can be permanently cured. Fourth, the wilfully betraying of a professional secret. Fifth, all advertising of medical business in which untruthful and improbable statements are made. Sixth, all advertising of any medicines or of any means whereby the monthly periods of women can be regulated or the menses re-established if suppressed. Seventh, conviction of any offence involving moral turpitude. Eighth, habitual intemperance.

MELANOTIC SARCOMA WITH GENERAL MELANOSIS.

By JOHN TRUMBULL, M.D.,

Valparaiso, Chili.

A year before B——, a man aged forty-four, called on me, an attempt had been made to remove a black mole, which, though existing from childhood, had then begun to grow. The ligature occasioned considerable pain and led to severe bleeding, so that he avoided medical men until its increase in size and ulceration rendered it annoying and painful. On the abdominal wall, in the left mamillary line, and at the level of the umbilicus, I found a mushroom-shaped black tumor the size of a silver dollar, with a red granulating surface over the part exposed to abrasion from the clothing. The pedicle was short and as thick as a man's finger. No enlarged glands were to be found in the groin. Of course, immediate removal was urged.

In the first operation, done in March, 1886, healthy tissue all about was freely removed with the growth, and union by first intention secured.

Sixteen months later I was called to attend my patient for a wrench to the arm, and found a couple of enlarged glands in the axilla, with, besides, two beginning spots of discoloration in the diminutive scars of two sutures which, in the first operation, had points of suppuration. On July 30, 1887, the old scar was removed and two large coal-black glands, of giant-celled sarcomatous growth, were taken from the lower thoracic side of the axillary region.

In October, 1887, a harassing cough brought him again under observation. Examination, on natural breathing, showed a decided difference in the respiratory sounds of the two sides of the chest, which disappeared on deep inspiration. No dulness was to be detected. It was feared that there were enlarged bronchial glands, but the cough yielded finally to morphine and hydrocyanic acid.

After this the patient persistently refused to allow himself to be seen till June, 1889, almost two years since the last operation, when examination disclosed extensive recurrence in the axilla. As there had been no return of the cough, no change in the physical signs, no enlargement of the liver, and nothing to contra-indicate operation, this was done, as many as twelve distinct glands being removed, which, on section were partly black and partly translucent. Within ten days, the wound had entirely closed, the axilla was soft, and the patient went to the country to gather strength.

Six weeks later he returned because of loss of sleep from shooting pains about the shoulder and elbow. There was decided loss of strength and flesh. Deep about the axillary vessels a tumor was felt, but at the same time the liver was found enlarged and tender. So, also, the right kidney. The urine was very dark, and, while without albumin or bile pigments, it turned black on exposure, or upon the addition of nitric acid. No sediment. Further operation was refused because of the general scattering of the malignant growth.

August 21st, when seen, the growth was about the size of a hen's egg, and within three weeks was as large as a man's head. The daily increase in size was manifest both to the sight and touch; and the rapid tissue-changes were manifest by a decided elevation of temperature. The patient, aside from the neuralgic pains, never ceased to complain of the great heat, and the thermometer verified the occasion of his complaints. In the left axilla the temperature was 103.1° F.; in the right axilla, 98.6° F.; and in the mouth, 99° F.

It looked as though the black irregular mass would burst through the scar, but fortunately the rate of increase during the last weeks fell off. The liver continued to

grow in size, the splenic dulness increased, and the left chest especially showed signs of encroachment by the disease. Later on, vomiting appeared, mental disturbance, insanity of persecution, irregular pulse, blunting of sensibility, and slow death by inanition, which occurred on October 14th.

The pigment which the urine led one to believe was circulating in the blood soon showed itself by a discoloration, first of the nail-beds, and later of the whole surface. The patient, a very white-skinned man, before death became as black as a West Indian, only that the color was a bluish black.

The case seems of interest, therefore, because of :

1. Length of time that a giant-celled melanotic sarcoma was allowed to remain, and yet that repeated operations gave a lease of life for three and a half years.

2. Though free removal of apparently healthy tissue was made, recurrence at the site of the original growth took place in points irritated by suppuration of two sutures.

3. Lymphatic drainage toward the axillary glands from a point so low on the abdominal wall.

4. Final rapid growth with such increase of local temperature.

5. General staining of the surface of the body from pigment circulating in the blood.

CHLOROFORMING THE SLEEPING.

By L. A. KELLY, M.D.,
WINONA, MINN.

The discussion in the MEDICAL RECORD of the effects of chloroform administered to persons while sleeping calls to mind an experiment of my own. Some two years ago I had occasion to remove a piece of catheter from the bladder of a young man, fifteen years of age. The accident happened in the morning, and I arrived at the place about midnight of the same day, to find the patient sleeping soundly and sweetly, having been asleep for fully two hours.

The subject and his necessity seemed to warrant the propriety of an experiment, if such it may be called. Without awaking him, I began to administer chloroform in the usual way. Much to my surprise, sleep continued undisturbed by the anæsthetic, not the slightest movement of limb or muscle indicating consciousness. The breathing only was slightly affected, as the sleeping passed from natural to the artificial.

The operation concluded and the chloroform suspended he was aroused with some effort by his friends. This subject had not suffered previous loss of sleep, and presented no evidence of previous exhaustion or ill-health.

Progress of Medical Science.

Two Cases of Diabetes Mellitus in Children.—The prognosis of this affection varies greatly according to the period of life at which it appears. In advanced age its progress may be greatly retarded by proper treatment. In early youth, on the contrary, its course is very rapid, and death soon closes the scene. The nature of the disease, process, or processes, on which this symptom depends is not yet understood, and in many cases in young patients no treatment seems to be of any value.

In the *Archives of Pediatrics*, October, 1889, Dr. Allen reports two cases of the disease occurring in children. In the first case, a boy, three and a half years of age, unusually bright, and previously healthy, the child of a robust father and of a nervous mother, was observed to pass an unusual quantity of urine, occasionally wetting his bed, but was supposed by the family physician to have only a catarrh of the bladder, as he seemed otherwise well. Six months later, as his micturition was very frequent, Dr. Allen was consulted. He was now weak and peevish, with marked thirst, cold limbs, and dry skin. The daily excretion of urine anounted to four quarts. Its specific gravity was 1.028, and it contained sugar. He was removed to the city and treated with reduced iron and opium, Hunyadi Janos and Sprüdl, starchy food being withheld. In consequence of change of air and diet, and of the use of the remedies mentioned, the quantity of urine and the amount of sugar became rapidly less, although the specific gravity increased. A week later, in consultation, the chloride of gold and sodium, and the phosphate and arsenite of soda were given instead of the drugs at first prescribed.

A week after this the patient was found to have lost flesh and strength, and to have taken to his bed, sleeping most of the time, but quite intelligent when aroused. The patient suffered little from thirst, but complained bitterly of hunger. A milk diet was now enforced, but the amount of sugar was not lessened thereby. He failed rapidly, with pain in the bowels and delirium, and died about four weeks after he came under Dr. Allen's care. During the twenty-four hours preceding death he lay in continuous stupor, passing hardly any urine. The autopsy disclosed nothing abnormal in the thoracic and abdominal viscera, and in the cranium only an increased amount of subarachnoid fluid, and slight opacity of the lining membrane of the lateral ventricles of the brain. The brain was unusually large.

The second patient, a boy, seven years of age, of fair health, whose father and mother were healthy, but whose great-uncle and two great-aunts had died in middle life of diabetes, was brought for treatment, as he had for more than a month been languid and thirsty, rising many times each night to urinate. His appetite was voracious, but he was very thin. Two or three quarts of urine were passed each day. Its specific gravity was 1.040, and it contained a large amount of sugar. He was treated with iron, opium, Hunyadi Janos, and Sprüdl, and non-farinaceous diet was instituted. Ten days later he was passing a quart of urine in twenty-four hours, of lower specific gravity, and containing less sugar, and he seemed to bear his diet well and get stronger on it. He was removed to Minnesota. After a temporary improvement he became tired of his diet and lost strength, although the amount of sugar did not again increase. He died about three months after he was first seen by Dr. Allen.

The Transmission of Typhoid Fever by the Air.—It has come to be generally admitted that the transmission of typhoid fever takes place principally, if not exclusively, through the water-supply. Experience, indeed, has proved this to be the case, but it must not be overlooked that other ways may exist, notably by the breathing of air contaminated with the spores of the typhoid bacillus. Some observations by Dr. Chour, of an epidemic of typhoid fever among soldiers, commented upon in the *Revue Scientifique*, serve to show the importance of not concentrating one's attention too exclusively upon any one vehicle in the endeavor to prevent the spread of the disease. Two regiments stationed at Jitomir, and supplied with drinking-water from the same source, suffered in a very different degree from the disease. The soldiers belonging to the regiment which suffered most severely were quartered in various barracks, and it was remarked that at one particular locality the men were attacked in far larger proportion than their fellows who were located elsewhere. In December, 1886, the buildings were evacuated and thoroughly cleansed and disinfected, whereupon the mortality fell to 1.7 per 1,000 in 1887, and *nil* in 1888. In the other barracks, which had not been thus dealt with, the mortality rose to 22 per 1,000 in 1887, and 33 per 1,000 in 1888. It occurred to Dr. Chour to institute an examination of the dust from the infected barracks, and he found therein an average of fourteen million microbes per gramme, among which the typhoid bacillus was easily detected. The evacuation of the rooms and their thorough disinfection promptly put an end to the epidemic.—*Medical Press.*

Creasote in Tuberculosis.—Professor Sommerbrodt declares that an experience of over five thousand cases has now proved to his own satisfaction that creasote is not merely a useful drug for the symptomatic treatment of tuberculosis, as has been conceded by others, but that it exerts a specific influence on the disease by the resistance it offers to the cultivation of tubercle bacilli. Dr. P. Guttmann had, by his experiments, shown that tubercle bacilli could scarcely be cultivated in sterilized serum containing $\frac{1}{4000}$th of its volume of creasote, and the culture entirely failed when the solution was a little more concentrated. He concludes that if it were only possible to administer sufficient creasote for the blood to contain that drug for some time in the proportion of $\frac{1}{4000}$th of its own quantity, tubercle bacilli would probably cease to develop. This, he contends, is impossible, not only because the required quantity of creasote in the blood would be more than twenty grains, but because it would be impossible to determine what quantity of creasote would have to be administered to make twenty grains of it circulate in the blood. Sommerbrodt believes that it is possible to give the necessary quantity of creasote. He has been prescribing for some time to many hundreds of tuberculous patients capsules of creasote, each containing one grain of the drug. These capsules were taken, three the first day, and every succeeding day one more, until the eighteenth day, after which the same quantity—from twenty to twenty-five grains per day—was continued for many months. The author says it is impossible to presume that the twenty grains of creasote have already entirely passed out of the blood by the time the second or third dose of the drug is given, so that probably such an accumulation of creasote takes place in the tissues as to fulfil Dr. Guttmann's postulate. He has at any rate had the most gratifying success with this medication, and his experience was that the more creasote a patient could bear in a day the greater was this success. The *modus operandi* of the creasote, Dr. Sommerbrodt says, has not yet been sufficiently cleared up. The drug is certainly a stomachic tonic, and diminishes the secretions, but these can hardly be its chief effects. He rather believes, although the experiments on animals have so far led to negative results only, that a sufficient quantity of creasote must make the soil unsuitable for the cultivation of tubercle bacilli. He suggests, therefore, that serum from a man who has for some time taken more than twenty grains of creasote be used to cultivate tubercle bacilli, so as to find if this acts differently from the serum of another person used for the same purpose—*Canadian Practitioner.*

Treatment of Eczema, Psoriasis, and Pityriasis.—At the International Congress of Dermatology and Syphilography, Dr. Gourbault reported a number of cases of eczema, psoriasis, and pityriasis, which he had rapidly cured by the following sirup and ointment: Sixteen ounces of the sirup contain—of bicarbonate and acetate of soda two drachms each, also two drachms of extract of gentian, and a similar quantity of extract of sarsaparilla; a small amount of rhubarb and senna may be added at the physician's discretion. The dose should be two fluidounces daily. The formula for the ointment is as follows:

℞. Ergotine,
Perchloride of iron ..... āā ʒ ss.
Vaseline ..... ʒ j.
M. et fiat unguent.

This should be applied to the affected parts twice a day. —*Gaillard's Journal.*

The Treatment of Insomnia.—An address on the treatment of insomnia was recently given by Dr. Jastrowitz, at the meeting of the Society for Medicine, Berlin. He first spoke of the employment of alcohol in its various forms of wine, beer, and spirits. Alcohol is given as a narcotic in acute diseases, in cases where it is desirable to use one that is not a cardiac depressant. Alcohol is first a cardiac whip, and then, when the stimulant action has passed off, a "somniferum." But even if alcohol were useful in furthering sleep, the dread and nervous excitement are often increased in melancholic patients the following morning. Persons who have become accustomed to other hypnotics think on taking opium or morphine that the sleep following these is the most natural. These are indispensable sedatives in such cases as cancer and tabes. It is a noteworthy fact that opium and morphine are first sedatives, and hypnotics only in large doses; a third and very valuable property which they possess is that of a tonic. In congestion of the chest as well as in diseases of the heart great caution must be used, as both paralyze the heart; and in chronic insomnia the danger of setting up a dangerous and intractable morphine habit must be borne in mind. In senile insomnia opium acts better than morphine; it is superior also in intestinal diseases and in certain forms of melancholia and mania. Jastrowitz has used it gladly in delirium tremens. Chloral hydrate has the advantage of being the most powerful of all hypnotics: it never fails. Sulphonal is distinguished by absence of odor and taste, so that it can easily be given to unwilling patients. All observers are agreed that it does not affect the heart. Its action, however, is very slow, so that it is not so suitable for acute affections. Neither does it relieve pain, but, on the other hand, no other drug can replace it in cases distinguished by motor restlessness, such as chorea. In mania, sulphonal is best given as a dose of 7½ to 15 grains during the day, and another dose in the evening. The sleep after sulphonal most closely resembles the natural.—*The Medical Press.*

The Influence of Ventilation on the Micro-organisms Floating in the Air.—According to Dr. Stern it is *a priori* to be expected that the influence will depend very much on the character of the ventilation. His opinion, being founded on direct experiments, will bear a value proportionate to the known reliability of the experimenter. He found that when the air was still the germ-bearing dust rapidly fell to the ground, so that in the course of an hour and a half the air was practically free from germs. Lighter material—wool, the spores of fungus, etc., required a longer period to settle down. The most powerful ventilation in ordinary use, that in which the air of a room is renewed three times in the hour did not make the air more rapidly free from germs than simple settling. One more powerful is scarcely possible without creating a draught, but it becomes gradually more effective in proportion to its strength. Its action in removing germs rapidly becomes effectual when a rapidity of six or seven renewals of the air of the room per hour is reached. It was not observed that the rapid entrance of fresh air removed to any extent the germs from the floor, carpets, furniture, or clothes. Steam was not successful in producing a rapid deposit of the suspended germs, at least not to any great extent.—*Zeitschrift für Hygiene.*

Rupture of the Gall-bladder in Infants.—M. Hayem gives a short history of a baby, aged two months, under his care, who during the second month of her life had been jaundiced to a moderate extent. The jaundice was accompanied with frequent subcutaneous hemorrhage round the umbilicus and on the lips and ears. The autopsy showed that the abdominal cavity was full of a fluid resembling bile, which seemed to have come from the gall-bladder, in which was a small recent wound imperfectly healed. The surface of the peritoneum and the mesenteric glands were deeply stained. M. Hayem considered the lesion traumatic, and thought it interesting as being practically an experiment showing the effect of aseptic bile in producing a hemorrhagic tendency. M. Ollivier had often remarked the extreme thinness of the walls of the gall-bladder in infants, and noticed that rupture was an occasional cause of death in typhoid fever by producing peritonitis.—*The Practitioner.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, March 29, 1890.

HEART DISEASE OF THE AGED.

EVERYONE knows how apt the aged are to die suddenly during the course of a mild bronchitis, or after a comparatively slight traumatism, even when they may seem to be progressing favorably toward recovery. Some old people, it is true, are most tenacious of life, and will recover from injuries that would ordinarily be fatal to much younger and seemingly stronger men; yet others, and perhaps the majority of those who have passed the scriptural limit of threescore years and ten, have but a very weak grasp upon existence in this world, and relinquish their hold upon it often without any apparently sufficient reason. This often comes from a weak heart, and it is quite common nowadays to hear of "heart-failure" given as the cause of death in aged persons.

In a paper read before the Paris Academy of Medicine on February 18, 1890, Dr. Renault, of Lyons, described a form of heart-trouble which is very common in the aged, and which he regards as the most frequent cause of heart-failure and of death in those of advanced life. This disease he calls chronic essential segmentary myocarditis, and its essence consists in a dissolving away or loosening of the cement which normally holds together the muscular segments of the myocardium. This is the only lesion in the pure cases of the disease; there is no fatty degeneration or infiltration of the heart, no cirrhosis of this organ, no accompanying catarrhal diseases of the mucous membranes, and no affections of the arteries, beyond the more or less marked atheroma, which may be looked upon as almost a normal condition of senility.

The symptoms of the affection are very clear, and serve to distinguish it from all other cardiac diseases. The first and most constant sign is irregularity in both the cardiac and the radial pulsations. Of this arythmia there are two forms, one most clear and unmistakable, the other apt to be overlooked unless the observer be on the watch for it. In the latter the pulse may seem perfectly regular to the touch, and even auscultation may not reveal the want of rhythm in the heart's contractions, but sphygmographic tracings show plainly that this condition exists, and the pulsations are seen to be neither equipotential nor equidistant. In the former variety the pulsations are irregular to the last degree, and not only does one pulsation differ from the preceding or the following, but one series of pulsations will differ from another, so that various sphygmographic tracings taken on the same individual at different times bear no resemblance whatever to each other. A second sign is the impossibility of locating the apex beat. This is felt in the usual situation, but it is diffuse, and it is impossible to put the finger on any one spot and say that there is the apex beat. A third symptom is that the area of cardiac dulness is rectangular in shape. The outer edge of this square extends from the fifth upward to the third intercostal space, keeping always within the line of the mamma; the inner edge extends along the border of the sternum from the sixth or seventh chondrosternal articulation to the third interspace. Two transverse and parallel lines, connecting these vertical lines, form the upper and lower borders of the rectangle. Auscultation furnishes us with still another valuable sign in many cases. In addition to the evidence of an arythmic action of the heart which this gives, there is often heard a characteristic murmur. This is a systolic sound heard over the centre of the heart at an equal distance from both apex and base, and never propagated any distance to one side or the other. It is never accompanied by any musical sound, but is a soft and often scarcely perceptible blowing. Another peculiarity of this murmur is its instability, for it often disappears for months at a time, and then comes back when a light bronchitis or other cause is present, to throw more work upon the weakened heart. Contrary to what obtains in organic affections of the heart which have progressed to the stage of weakness of the myocardium, as shown by the irregular pulse, there is no tumefaction or sensitiveness of the liver, nor is there any venous stasis or engorgement of the right side of the heart. At the most there may be a very slight degree of œdema about the malleoli, and sometimes careful examination reveals a moderate amount of pulmonary œdema confined to the base of the lungs, usually to that of the left lung.

Death occurs in these cases either in sudden syncope or by asystolia. The author has never observed rupture of the heart in those suffering from segmentary myocarditis, and he attributes this to the fact that, although there is a weakening of the heart-wall, there is nevertheless no cirrhosis, no increase of the intermuscular connective tissue, which has been shown by Robin to be one of the essential conditions of this accident. As before stated, the affection is essentially a senile disease, but it is also seen in those prematurely aged by the abuse of alcohol, by gout, or by some other chronic affection.

In the treatment of this condition Dr. Renault relies mainly upon digitalis, general tonics, and stimulants. The subjects of this disease are especially vulnerable, and should be protected with the greatest care against all injurious influences, especially bronchitis, which is so apt to prove fatal to the weakened heart. Whenever bronchitis attacks one of these patients the author has recourse at once to digitalis and to ergot, the latter as a special arterial tonic. In addition, champagne is often of the greatest service.

THE EXPERIENCES OF A BOTANIST AND PHYSICIAN IN SOUTH AMERICA.

AT a reception given by Mr. William H. S. Wood, on Monday evening last, Dr. H. H. Rusby entertained the guests with a most interesting account of his experiences

while on a two years' botanizing expedition in South America.

Dr. Rusby's route was along the Pacific coast to the southern part of Peru, where he went inland across the Andes to the Madeira River, and then descended that river and the Amazon to the Atlantic coast. He encountered many kinds of climate, and sometimes the changes were sudden and great, so that, starting in the morning from a region of snow and ice, before evening he would find himself surrounded by banana and orange trees and all the rank vegetation of the tropics. No greater contrast could be imagined than what is to be found between the east and the west sides of the Andes. On the Pacific side rain is almost unknown, the soil is a fine sand, and the whole country is a veritable desert. The climate is a most healthful one, and is especially adapted to the treatment of pulmonary diseases, such a thing as phthisis being practically unknown in that region. If it were not for the indescribably filthy habits of the natives of the country death from disease would be a most rare occurrence. But on the other side of the mountains rain is constant, a day seldom passing, even in the so-called dry season, in which there is not more or less rain, and during the remainder of the year there is one almost uninterrupted downpour. The climate is raw and bleak. The natives are a well developed and sturdy race, and the most industrious, the speaker said, that he had ever seen. They will run long distances, carrying heavy loads on their backs, the women even spinning while they run, and never seem to tire; yet their industry brings them little, and they are so wretchedly poor that, in spite of the fact that it is a grazing country, they almost never taste meat. Their principal food is a vegetable resembling our spinach. One of the most common diseases of this region is heart disease, induced, it is said, by the running and mountain climbing. It would thus appear that mountain climbing may be as injurious to the heart, if indulged in too recklessly, as it is claimed to be beneficial when done moderately and according to medical prescription. Another common affection is one of the lungs, which occurs as a sequel to emphysema.

In passing from these high table-lands to the valley below the climatic change is exceedingly abrupt; the traveller may be walking through snow and ice, and shivering with the cold, and when he turns around the corner of a large rock immediately a warm breeze strikes his face, and in a short time he stops to rest in a tropical garden. A gentleman whom Dr. Rusby met there could gather ice and pick oranges on the same day on his own estate, so that his farm, as the speaker said, extended from the north pole to the equator. The natives of this region are large and powerful, but are affected by the climate, and have little of the energy and industry of their neighbors on the heights above. A peculiar disease from which they often suffer is characterized by the formation of ulcers, of variable size, resembling somewhat soft chancres, with slightly infiltrated, but never indurated, edges. These ulcers are found on the shin, forearm, back of the hand, and in other places. It is seldom that any treatment is effectual in arresting the disease when once it has commenced; the ulcers continue to increase in size and numbers, and finally the patient dies from exhaustion. The vitality of the inhabitants of this portion of the world is very low; the adults are apparently robust, but when once they are attacked by disease they die almost without a struggle. Often the inhabitants of a certain region will nearly all die, even when there is no epidemic to carry them off, and they die simply because they have no resisting power, no hold upon life.

Dr. Rusby had an opportunity of noting the prostrating effects of disease in this country in his own person. He was attacked by a malarial fever on one occasion, but did not consider himself very sick, and was a little surprised, and even amused, to note the seemingly undue anxiety of those about him. He had, he said, often had malaria in New Jersey, and apparently in a much more severe form, and he was rather congratulating himself upon the mildness of his present seizure. The next day, however, although the fever was gone, he found himself utterly prostrated, and it was a long time before his strength was sufficiently restored to enable him to be up and about again. An interesting fact mentioned by the speaker was that there was but little danger of malaria in sleeping near stagnant pools, but that a sojourn near running streams or waterfalls was almost sure to be followed by a seizure. This would seem to argue in support of the theory advanced some time ago, that the malarial poison is carried by running water from wooded regions and that marshes are not its natural habitat. One potent cause of the lowered powers of resistance to disease, which is so noticeable in the natives of the country, is the wearing effect upon the nervous system of the continual attacks of insects. These creatures are the great scourge of the land. Ants, mosquitoes, gnats, jiggers, fleas, and myriads of other varieties are present everywhere, and the suffering caused by their bites is something that beggars description. There is no rest from their attacks by night or day. The bites of many of them cause not only annoyance but acute suffering, and it is easy to imagine the depressing effects upon the nervous system of such a continual warfare with these invincible, though almost invisible, foes. The natives have many strange customs—such as worshipping pieces of wood, not fashioned into any shape of man or beast, but simply in the natural state or only polished, during the rainy season, and worshipping stones during the dry season; playing a game of ball in which the player's hip serves as a bat, chewing of coca leaves by the men alone in the temples, as a form of worship, etc.—to which Dr. Rusby referred, but which we cannot do more than allude to here. In regard to the effects of coca-chewing, concerning which travellers relate such wonderful tales, the speaker said that they were undoubtedly true. The porters of goods over the Andes will go sometimes for two or three days with scarcely any food if only they have a supply of coca-leaves. There is apparently some substance in the fresh leaves which is of a volatile nature, and consequently is not found in the dried product, upon which this stimulating property depends. The amount of cocaine seems to have no influence upon the stimulating effect of the leaves, for in two specimens, one of which was pronounced good by the natives and the other bad, the proportion of cocaine was the same. Dr. Rusby was unable to detect any injurious effects from the habit of chewing the leaves. The men would not work as well when deprived of the plant, but there was no depression, and none of the symptoms seen in those addicted

to the cocaine habit. There was much else of great interest in Dr. Rusby's informal talk which we are obliged to pass over without even mention, but we hope that his labors in his chosen science will not be so exacting as to prevent him from writing an account of what he saw in this little-known country for the benefit of those who are able to see the strange parts of the world only through the eyes of others.

THE BILLS FOR BOARDS OF MEDICAL EXAMINERS.

There are at present before the Legislature at Albany two bills providing for the creation of State Boards of Medical Examiners. One of these provides for three independent Boards, a Regular, a Homœopathic, and an Eclectic; the other provides simply for one Board, before which all persons who wish to enter upon the practice of medicine in this State must come.

The lay press is somewhat divided in its opinions upon these measures. The *Herald*, whose editorial writers usually develop rare powers of misconception and a singular breadth of ignorance when medical topics are discussed, advocates the triple Board bill. The *Sun* urges the establishment of a single Board, and rightly says that the public is not interested in supporting and paying for peculiar therapeutical fashions, but is only desirous that its licensed physicians should be thoroughly grounded in the elemental branches of medicine.

This, we believe, is the view which sensible people will eventually adopt. The State will see that men who are to be entrusted with their health and lives are persons who have sufficient natural endowments to master the knowledge of anatomy, physiology, chemistry, obstetrics, surgery, and pathology. If they are well equipped in these respects, it need never fear that they will run after any therapeutical fads or fancies to an extent detrimental to public safety. A good preliminary education and a sound training in the medical sciences, is what regular physicians ask the State to insure to the people, and one Board of Examiners is enough to carry out this purpose.

A YEAR'S STUDY OF THE HEART.

A review of the contributions to the physiology and pathology of the heart and blood-vessels is to be found in the issue of *Schmidt's Jahrbücher* for February, 1890. The author is Dr. Schmaltz, and it is needless to say that he deals with the subject in a scientific, not a sentimental manner.

In the year 1889 the heart, popularly so called, has poured itself forth in hundreds of pages of poetry, oratory, and devotion, but the anatomical viscus has given rise to just one hundred and eight medical observations, collected and analyzed as above stated. Nearly half of these concern the general pathology and symptomatology of heart affections. The physiology of the heart, its neuroses, its special valvular lesions are discussed in eight or ten articles respectively. But little, we regret to say, has been added to the pathology of disease of the vessels, although medical writers continue copiously to report cases of aneurisms which have but a passing interest and no permanent value.

Under the head of general pathology we find one writer, Kirch, confirming the view of Nothnagel that arythmia is not a frequent characteristic of fatty heart. Several writers have discussed the curious cases of very slow pulse. Balfour has tried to draw a clinical picture of the "senile heart," which, he says, is characterized by abnormal frequency, or slowness or irregularity of action, with sometimes an abnormal accentuation of the heart-sounds (embryocardia).

The contributions to therapeutics include articles upon strophanthus, digitalis, spartein, milk sugar, massage of the heart, and the Oertel cure.

News of the Week.

The Wisconsin Training School for Nurses in Milwaukee has retired from the County Hospital, owing to a disagreement with the authorities of the institution, and will probably take up its quarters in the Passavant Hospital.

Medical College Commencements.—Graduation exercises have been held in the following schools during the past week: Medical Department of the Arkansas Industrial University, Little Rock, Ark.; College of Physicians and Surgeons, Baltimore, Md.; Michigan College of Medicine and Surgery, Detroit, Mich.; Albany Medical College, Albany, N. Y.

Denver has recently organized two new societies, the Obstetrical and Gynecological Society, and the Medico-Legal Society.

A Medical Postmaster.—Dr. Thomas Kelley, of San José, Cal., has been appointed postmaster in that city.

The Oldest Freemason in the World is said to be Dr. William Salmon, of England, whose age is over one hundred years.

An International Congress of Female Physicians.—Some of the medical women of Chicago are agitating the question of organizing an international congress of women physicians, to be held during the World's Fair in 1892 or 1893, and a committee is preparing a circular to be sent to the women physicians of all nations, which will fully outline the plan of work.

Trouble in Girard College. — Charges have been brought against many of the prefects of Girard College, Philadelphia, and they are accused of great cruelty to the boys under their care.

The Medical Staff of the Philadelphia Hospital.—The Civil Service Association of Philadelphia has, through its attorneys, applied to the Attorney-General to obtain a writ of mandamus to compel the Mayor and the Board of Charities and Correction to fill the positions on the medical staff of the Philadelphia Hospital in accordance with the provisions of the amended city charter (called the Bullitt law). It is claimed that the election of Visiting Physicians held by the President and Directors of the Department of Charities and Correction on December 31, 1889, was legally ineffective, and that the Visiting Physicians then appointed have not thereby acquired legal titles to their offices.

Typhoid Fever in Bolivia.—A letter from San José de Costa Rica states that typhoid fever is raging in La Paza, Bolivia. Over three thousand cases were reported during a single week.

The Eruptive Hospital in Louisville, Ky., is to be placed under the care of the Sisters of Charity.

The Massachusetts Association of Boards of Health.—A meeting of about fifty gentlemen, representing various boards of health in Massachusetts, was held in Boston, on March 19th, to organize a State Association. According to the constitution the name of the association is the Massachusetts Association of Boards of Health. The object of the association is the advancement of sanitary science in the State of Massachusetts, better organization and co-operation in the local boards of health, and the uniform enforcement of sanitary laws and regulations of the various boards. Any person holding an appointment as a member of the board of health in a city or town in the State may become a member of the association. Dr. H. P. Walcott, of Cambridge, was chosen *President;* Dr. Durgin, of Boston, *First Vice-President;* L. F. Woodward, of Worcester, *Secretary;* and Dr. J. B. Field, of Lowell, *Treasurer.*

Thirty Thousand Dollars for a Hospital.—Hon. George A. Pillsbury, of Minneapolis, ex-mayor and twenty-seven years a resident of Concord prior to 1880, has given $30,000 to the Concord Hospital Association for a new building, to be named the Margaret Pillsbury Hospital, as a memorial to his wife.

A Dangerous Hugger.—There is said to be a girl in Genesee County, in this State, whose strength is so great that when she hugs a man she always breaks one or more of his ribs. When she drives with a young man she is always asked to take the lines.

In Diabetic Coma, Dr. Dickinson has shown that large intravenous injections (100 oz.) of a saline solution restores consciousness temporarily.

The Influenza Epidemic has in some localities largely increased the number of suicides. Seventy-five occurred in Berlin in the month of February.

The International Medical Congress.—The invitations and preliminary departmental programmes for the International Medical Congress, to be held next August are now ready, and are to be sent this month. The organization committee of the department for general pathology and pathological anatomy, of which Professor Virchow, the President of the Congress, is the head, has selected the following themes for discussion: (1) Lesions of the Myocardium; (2) The Share taken by the White Blood-corpuscles in the Formation of Tissues; and (3) Tuberculosis.

A Case of Long Memory.—The treasurer of the Royal Westminster Ophthalmic Hospital has recently acknowledged the gift of $250 from an anonymous donor, signing himself "Grateful," in recognition of a successful operation performed on his father, upward of fifty years ago, by the late Dr. Guthrie.

The Memorial Hospital at Scranton.—It has been authoritatively announced to the managers of the Moses Taylor Memorial Hospital, at Scranton, Pa., that it is the purpose of Mrs. Taylor to contribute an endowment fund of $250,000, the income of which shall be used for the maintenance of the hospital. The various members of Mr. Taylor's family have now contributed $650,000 to the hospital.

The California State Medical Society meets at Los Angeles, April 15, 16, and 17, 1890.

The Mississippi State Medical Association meets at Jackson, April 16th.

The Tennessee State Medical Society meets at Memphis, April 8th.

The Arkansas State Medical Society meets at Little Rock, May 14th.

We learn that there is a Medical College in Jersey City. It is called the New Jersey Medical and Surgical College, and it recently graduated a class of three.

Bellevue Hospital Medical College held its Commencement, March 10th, graduating one hundred and forty-four students.

The Meeting of the Association of American Physicians has been changed to May 13th, 14th, and 15th.

A "Cynophile" is the latest name for the "dog-loving" anti-vivisectionist.

The Influenza has recently appeared in the Bermuda Islands.

A Uniform Standard for Admission to State Medical Societies.—At its last quarterly meeting the Rhode Island State Medical Society adopted the following resolution, viz., "That the President of the Rhode Island Medical Society shall be authorized to open negotiations with the medical societies of such other States as have a system of entrance examinations similar to our own, to have an agreement between the different State societies arrived at, by which membership in any one of the agreeing State societies shall be sufficient proof of qualification to become, upon application, a member of any other State society without further conditions of admittance. And also to have in the agreement a clause incorporated which will admit, upon application, to membership in any of such corresponding State societies, the members of the medical and surgical staffs of the United States Army and Navy without further conditions of admittance." The plan above suggested is an interesting one, and deserves the attention of our State medical organizations.

The United States Government Hospitals at the Hot Springs.—The association in the public and professional mind of the Arkansas Hot Springs with the treatment of syphilis is a very general one, and is pretty substantially founded. The proposal by Congress to establish a hospital there for the "rheumatic" veterans of the National Soldiers' Homes will strike one, therefore, as being highly interesting. The United States Government has already an Army and Navy Hospital at that place, so that those in active service can receive treatment for their exposures and indiscretions. The Government's final step will be, perhaps, to have a hospital there for its civil employees.

The Medical Colleges of the United States will be represented at a conference to be held at Nashville, Tenn., in May next, at the time of meeting of the American Medical Association, to consider the following points: 1. Three years' course of six months' session. 2. Graded curriculum. 3. Written or oral examinations. 4. Preliminary examination in English. 5. Laboratory instruction in chemistry, histology, and pathology.

Dr. Charles F. Stillman, formerly of this city, is now practising in Chicago, Ill.

The Indiana Medical College has lengthened its course of study to three years and its term to six months.

Hygiene at the University of Pennsylvania.—A new building is about to be erected at a cost of $50,000, for the department of hygiene at the University of Pennsylvania. An endowment fund of $200,000 for the new department has been raised by individual subscriptions.

A Hospital in Langholm, Scotland.—Mr. Thomas Hope, who died at Noroton, Conn., on March 3d, left by his will about $400,000 to found a hospital at Langholm, Scotland, where he was born. Mr. Hope came to this city when a boy and made a fortune in the grocery business, having founded the present house of Acker, Merrall, & Condit.

Examinations for Foreign Physicians.—At the recent monthly meeting of the Kings County Medical Society the Council recommended that, in the sense of the Society, diplomas from foreign medical colleges should not entitle the holders to practise without an examination. The reading of this section of the report of the Council gave rise to some discussion, but it was finally adopted.

Dr. William C. Lane, of Mercersburg, Pa., died in that place a few days ago, aged sixty-five. Dr. Lane was a graduate of the University of Pennsylvania and served as surgeon in the army during the war of the rebellion. He has left a wife and five children.

A Project is on foot to establish a charity hospital in San Francisco.

Material for Dissection.—In a petition to the Senate in favor of the passage of a bill giving the bodies of unclaimed dead to the medical colleges, and which was signed by a number of physicians of the District of Columbia, it is stated frankly that in the District of Columbia, during the last sixty years or more, the bodies used for dissection have been surreptitiously obtained, often enough at the risk of life and limb as well as liberty.

Information for Medical Students in Berlin.—Last year the Young Men's League of the American Church in Berlin announced that it would gladly assist any young men who were coming to Berlin to attend the University, or any of the various schools of art and music, and who desired information in regard to studies, expenses, rooms, and boarding places. Quite a number took advantage of this offer and received valuable assistance. The League is still ready to be of service to new comers, and so would make the same announcement this year. Application by letter or in person may be made to W. H. Manss, Bülowstr., 18, I; to H. F. Gilt, Wilhelmstr., 118, III, or to C. M. Clark, Teltowerstr., 23, I. This special committee will act till August 1, 1890, after which date inquiry should be made for the president of the League at the Y. M. C. A. building, Wilhelmstr., 34, Hof.

Yellow Fever in Brazil.—A cablegram from Paris states that yellow fever has broken out in a number of the towns along the coast of Brazil.

Dr. J. W. Jackson died recently in Kansas City. He was born in Virginia, but studied medicine in St. Louis, where he obtained his degree in 1864.

Sir William Gull left a fortune, so it is stated, of considerably over one million dollars. If this is true his estate is in striking contrast to those of most medical men.

The Alabama State Medical Association will hold its annual meeting at Birmingham, on April 8th. The question of contract practice will be a prominent one at this meeting. It is now a rule of the association that no member shall do contract practice. The present contract surgeon of the Cahaba Coal Mining Company, at Blocton, sent his resignation to the association at the time he accepted the position with the company, but the resignation was not accepted, and the surgeon was suspended. It is thought that he will now test the right of the Board of Censors to expel him, on the ground that he sent in his resignation before he had violated any rule.

The Italian Maritime Hospital was opened in Brooklyn on March 16th. It is located at 141 Harrison Street, in a building formerly used as a private dwelling. It contains fourteen rooms for the use of the patients. In the basement are a laboratory, physician's room, bath-rooms, kitchen, and store-rooms. On the first floor are two reception-rooms, a parlor, and two large patients' rooms. On the second or top floor are two rooms reserved exclusively for the use of sea captains. According to the by-laws of the hospital a tax of nine dollars is levied personally on every Italian sea captain sailing between this and foreign ports every time his vessel touches at this port. This money is used for the maintenance of the hospital, which is a free institution. This tax is said to be paid cheerfully by the captains.

Dr. B. Sweeny, of Du Bois, Pa., died in that place on March 11th, in his seventieth year. He was the eldest practitioner in that part of the State.

The Leprosy Settlement at Tracadie.—A report on leprosy at the lazaretto, Tracadie, N. B., has been presented to the Ottawa Government by Dr. A. C. Smith, visiting physician of that institution. He reports twenty persons suffering from that disease now in the lazaretto, and three deaths as having occurred during the year. Leprosy, he states, is dying out in Tracadie, but as cases were reported appearing in the neighboring districts, Dr. Smith made a special tour of inspection, which resulted in his finding a focus of the disease between Caraquet and Shippgun, and he traced from this centre several cases to other settlements. The doctor urges permanent measures of segregation as the only means of stamping out the disease.

The Brain of Laura Bridgman, the celebrated blind and deaf-mute pupil of Dr. Howe, is being carefully examined at Clark University, Worcester, by Dr. Donaldson, who, it is said, will shortly publish the results of his study.

Where Medical Practice is Fraught With Danger.—Reports from various parts of the Western country have appeared recently in the papers of the killing of several "medicine men" by the Indians, because of bad luck in the management of their cases. If their patients recover the medicine men are a power and command the respect of the tribe, but when they are unsuccessful their lives are often sacrificed. After all, the difference in the treatment of his physicians by the savage red man and his civilized white brother is rather one of degree than of kind.

New York Post-Graduate Medical School and Hospital.—The following additions have been made to the Faculty of the New York Post-Graduate Medical School and Hospital: Charles B. Kelsey, M.D., Professor of Rectal Diseases; Charles H. Knight, M.D., Professor of Laryngology and Rhinology; Reynold W. Wilcox, M.D., Professor of Clinical Medicine; Dr. S. Lustgarten, formerly Privat Docent in Vienna University, Instructor in Syphilis and Dermatology.

New York Ophthalmological Society.—At a recent meeting of the New York Ophthalmological Society, the following officers were elected to serve for the ensuing year: S. B. St. John, M.D., Hartford, Conn., *President;* H. S. Oppenheimer, M.D., *Vice-President;* John E. Weeks, M.D., *Secretary and Treasurer.*

A Bill Exempting Physicians from Personal Taxation is before the Legislature of Mississippi. It meets with much opposition on the ground of class legislation.

Dr. Henry S. Schell, of Philadelphia, died at San Diego, Cal., on March 15th. He was a graduate of the University of Pennsylvania in 1857, and was fifty-five years old at the time of his death.

Midwives and Antisepsis.—By a recent ministerial decree midwives in Prussia are directed to observe the strictest antiseptic precautions in attending on lying-in women. A complete code of instructions on this head is furnished them, in which it is satisfactory to see that the nail-brush figures conspicuously.

France and the Berlin International Medical Congress.—The French Medical Press Association had the subject of the Berlin Medical Congress under consideration at their ordinary quarterly dinner on February 14th. No definite conclusion having been come to as to the attitude to be assumed toward the scientific gathering in Germany, the members of the Association decided that it would be advisable to fortify themselves for finally grappling with this important matter by an "extraordinary dinner," which was to take place on the second Friday in March. It is said that the funds of the Association are "amply sufficient" for this expense, a circumstance which justifies the hope that the dinner may be good enough to let counsels of peace and good-will prevail.

A Death During the Administration of Ether is reported from Nashville, Tenn. The patient was the wife of a physician, and ether was given preliminary to the opening of an abscess of the leg, but she died before the operation was begun.

Reviews and Notices of Books.

A Reference Handbook of the Medical Sciences, Embracing the Entire Range of Scientific and Practical Medicine and Allied Science. By Various Writers. Illustrated by chromo-lithographs and fine wood engravings. Edited by Albert H. Buck, M.D., New York City. Volumes I. to VIII. New York: William Wood & Co. 1885–1889.

From time to time, as the several volumes of this work have appeared, we have noticed them in these columns, but have been compelled to do so briefly, preferring to wait until the series was completed to give a general review of the whole work. Now that this time has come we approach the task with hesitation, and this for two reasons: First, because it is manifestly impossible for any one writer, however versatile he might be, to review critically and with judgment a work of this kind, embracing as it does articles on almost every topic even remotely connected with the science of medicine. The second reason is that such a review as the importance and merits of the Handbook deserve cannot be condensed within the ordinary limits of a journal article. A bare enumeration of the most important subjects treated of would make a good-sized pamphlet, and still nothing in the nature of a critical review would have been made. We shall not attempt, therefore, to do more than call attention to a few of the leading articles under each department of medicine, seeking in this way to indicate the general character of the work without expanding the notice to undue length.

The aim of the editor of the Handbook, as indicated in the sub-title of the first volume, was to make "a complete and convenient work of reference for information upon topics belonging to the entire range of scientific and practical medicine," this work being made up of a series of concise essays, arranged in the alphabetical order of the topics of which they treat, and prepared by writers who are experts in their respective departments. That he has in the main succeeded in his endeavor must be admitted. We cannot indeed praise every article in the work, but we can praise the work as a whole; for the general character of the articles is so excellent, and the Handbook so very nearly corresponds to what the editor tried to make it, that the failure of two or three of the contributors to treat their subjects in a satisfactory manner is forgiven, or most likely not noticed, by the majority of those who have occasion to turn to the volumes for information on any topic.

Most of the writers are men well known throughout the country for their superior ability and their special knowledge of the subjects allotted to them, yet we find also many new names, and some of them, indeed, the authors of not a few of the best articles in the whole treatise. The accomplished editor seems to have strongly developed that instinct, as rare as it is wonderful, of discovering new writers and good writers. Some of the most important subjects in the Handbook have been intrusted to hitherto unknown authors, and they have been treated in a masterly way, and one that will not fail to bring to the writers honor and fame.

Some of the principal anatomical subjects are: Ankle-joint, Aorta, Anomalies of Arteries, Anomalies of Muscles, Arthrology, The Ear, Uterus and Vagina, Blood-vessels, Brain, Spinal Cord, Cranial Nerves, Spinal Nerves, Sympathetic Nervous System, Lymphatic System, Prostate Gland, Shoulder-joint, Eye, Intestine, Thorax, Transposition of Viscera, Anomalies of Veins, Blood-vessels of the Brain, The Skin and its Appendages, Perineum (male and female), Anatomical Terminology, etc. There are also many special articles on applied anatomy, such as the abdomen, face, foot, thigh, intestine, axilla, neck, etc. Comparative anatomy likewise receives some attention, though rather incidentally than intentionally.

The articles on organic materia medica and medical botany (many of them beautifully illustrated) were written by Dr. W. P. Bolles, of Boston. They are excellent in every particular, concise yet giving all needed information, and models of what articles in a work of this kind ought to be. The same remarks apply with equal truth to the articles on inorganic materia medica written by Dr. Edward Curtis, of this city. Nothing could be better than the way in which the subject of materia medica in its entirety has been treated by these two accomplished authorities.

The subject of histology is another one that has been most ably treated by Dr. T. M. Prudden, of New York. His articles are full of information, but short and to the point. Dr. G. C. Freeborn, also of this city, contributes an eminently practical article on histological technique.

Physiology and Animal Chemistry are treated of in a large number of separate articles.

Dr. Charles Sedgwick Minot, of Boston, is the author of a number of excellent articles on embryology.

The chief contributor to the subject of pathology is Dr. W. T. Councilman, of Baltimore, who has a number of sterling articles.

The subject of bacteriology receives ample treatment in articles on Bacteria, by Wm. T. Sedgwick, of Boston; Staining and Cultivation of Micro organisms, by Geo. C. Freeborn, of New York, and others.

Most of the articles descriptive of the various parasites that may infest the human body are from the pen of Dr. Charles E. Hackley, of this city. The parasites of the skin seem to have been described by the writers on dermatological topics.

The latter subjects are, of course, very numerous. The syphilitic diseases of the skin are described in the article on Syphilis (one of the best in the whole book, by the way), by James Nevins Hyde, of Chicago.

There are a great many short articles, one or two columns in length, on therapeutic subjects, scattered throughout the volumes. These are written by various contributors, most of them being what we might call the regular writers, members of the staff as it were, of the Handbook. There are several names which appear very frequently throughout the eight volumes, and appended to articles on all sorts of subjects, and the editor seems to have had certain men upon whom he called to contribute short articles on minor subjects which required considerable reading and compiling, but not much original research. A large number of such articles are necessary in any work of an encyclopædic character, and those in this work strike us as being remarkably good.

Allied to materia medica and therapeutics is the subject of toxicology, to which considerable space is devoted.

A series of interesting and useful articles are those on diagnosis. They include the differential diagnosis of special systems, as of local lesions in the brain, pons, and spinal cord, and of valvular diseases of the heart, and also descriptions of particular methods of diagnosis and of special instruments used for diagnostic purposes.

The medical topics treated of are legion, and we cannot attempt to give a fair presentation of them in the space at our disposal. Among the contributors are some of the best known physicians in the country, and though the articles are not all of uniform excellence, they are thoroughly good and are certainly equal to any that we have seen in any similar work in which medical subjects, strictly speaking, are treated.

The same remarks will apply to the manner in which the surgical subjects in this work are treated. They are written by surgeons of eminence in this country and Canada, and cover the entire field of operative surgery and surgical pathology.

A good deal of space is devoted to military and naval surgery.

Among the writers on obstetrical and gynecological subjects we find so many of the leading authorities of this country and Canada, that it is impossible to enumerate them.

There are a few articles referring especially to life insurance, among which the most important that we have noticed in our examination of the Handbook are, Selections of Lives, Laws of Insurance, and Mortality.

The treatment of the neurological subjects has been intrusted to a number of well-known authorities in this branch of medicine.

The anatomy of the brain and spinal cord receives very exhaustive treatment, though in some of the articles the new nomenclature which a few enthusiasts are trying (vainly, we hope) to introduce is employed.

In ophthalmology we find a number of most excellent papers. No other department of medical knowledge is more strongly represented in the Handbook than is that of Ophthalmology.

As the editor of this work is himself a distinguished aural surgeon, we would naturally expect to find this department well cared for. Dr. Buck has written a few of the articles, though not as many as he would have written probably, had some other person been the editor of the work.

In laryngology and rhinology there are many contributors, the two names that appear with the greatest frequency being Delavan, of this city, and Mackenzie, of Baltimore.

Considerable space is devoted to a consideration of climatology and health-resorts, there being an article on each of these subjects, and also separate papers descriptive of the most important health-resorts and medicinal springs in the world; the former are accompanied in many instances by charts of the temperature, rainfall, prevailing winds, etc., and in the latter are to be found analyses of the waters. There is also a paper on medicinal springs in general by Beaumont Small, of Ottawa, Canada, giving the principal indications for a resort to them in the attempted cure of disease.

Most of the medico-legal subjects are treated of by lawyers well known as authorities in medical jurisprudence.

The papers on hygiene and state medicine are very well written, for the most part, and are as interesting as they are practical and instructive.

There are, finally, a large number of articles on miscellaneous topics, which cannot be classified, but which are, many of them at least, of very great importance to the physician, and could not have been omitted from a work of this encyclopædic character. The following are some of the subjects coming under this omnibus head: Ambulance, Apothecary, Artificial Limbs, Atavism, Cephalometry, Childhood, Old Age, Consanguinity, Contagion, Cosmetics, Deaf-mutes, Weights and Measures, Fahrenheit and Centigrade Scales, Longevity, Infancy, Idiosyncrasy, Personal Nomenclature in Medicine, Poisonous Reptiles, Mushrooms and other Poisonous and Edible Fungi, Preparation of Skeletons, Ptomaines, Prescription-writing, Railway Medical Service, Puberty, Teratology, History of Tuberculosis, Thought-transference, Veterinary Post-mortem Examinations, Wet Nurses, Wines, Spirits, and Beers, Pension Laws, Thompsonianism and Perkinism, Influence of Race and Nationality upon Disease, etc.

We have endeavored in this review, which, long as it is, is far too short to permit of justice being done to many of the invaluable papers, to give an idea of the Handbook, so that one might know, before having seen it, about what it contains. It has been possible to mention only a few of the contributors whose names meet us in looking through the six thousand and more closely printed pages, for there are in all more than three hundred of them. The illustrations, of which there are over five thousand woodcuts and thirty-four lithographic plates, are vastly superior to any that we have ever seen in any similar work. They are well executed, show what they are designed to show (a merit that all wood-engravings do not possess), and are new; we see some old friends here and there, but they are not numerous, and most of the cuts seem to have been specially executed for the articles which they illustrate. An index of nearly two hundred three-column pages makes accessible the vast amount of information contained in these eight volumes. The typography and binding cannot be surpassed, the type is beautifully distinct, the ink is a deep black, and the remarkable freedom from typographical errors bears witness to careful proof-reading. The Handbook, as we have said, is not perfect, but it comes so near to the idea of what such a work should be that we have not the heart to dwell upon the few imperfections that we have detected on close scrutiny, and which we have mentioned above. The whole work is one that reflects credit upon American medicine, and the editor, contributors, and publishers may well be proud of their respective shares in the making of the book.

Society Reports.

NEW YORK PATHOLOGICAL SOCIETY.

Anniversary Meeting, January 8, 1890.

WILLIAM P. NORTHRUP, M.D., PRESIDENT, IN THE CHAIR.

Bacillus Versicolor.—DR. T. M. PRUDDEN presented a series of test-tubes containing cultures of a new chromogenic bacillus, and made the following remarks:

This bacillus, so far as I am aware, has never been described. I have called it, for reasons which will appear in its description, Bacillus Versicolor.

It has been found several times, floating with other micro-organisms in the dust of the air about New York. But it has been found only in single examples, and in comparison with other aërial organisms is rare. It is a short, round-end bacillus, about 0.75 to 1 μ thick, and 1.5 to 2 μ long, occurring singly and in pairs.

It fluidifies nutrient gelatine slowly, shows very slight mobility in fluids, and grows best at ordinary room temperature. It is aërobic, and no spore formation has been detected. On solid culture media it forms at first a grayish translucent pellicle, which soon becomes of a marked but dull lemon-yellow color. It develops in all the transparent culture media, at first a pink and then a rich red color. This color gradually permeates the non-fluidifying culture media.

The media in which the red color is thus developed show with the spectroscope two sharply defined absorption bands between D and E, which in situation and appearance are almost identical with the bands of a moderately dilute solution of oxyhæmo-globin. The growth in general is moderately rapid.

On *gelatin plates*, after forty-eight hours, the deep white round or oval colonies are from .1 to .3 mm. in diameter. Under the microscope they appear nearly opaque, but have a greenish-yellow shimmer; the edge is sharp and slightly rough, the surface finely linear granular. The surface colonies, at first translucent and waxy, gradually assume a yellow color, and are slightly raised. They may, in seventy-two hours, become from 2 to 3 mm. in diameter, the surface is slightly wrinkled and cup-shaped from fluidification of the gelatine. In from four to six days the yellow discodial colonies float about in a pit of turbid fluidified gelatine.

In *agar tubes* the growth on the surface is at first of a translucent grayish-white color, smooth and shining. Later it may spread to from 3 to 5 mm., forming a slightly raised yellow pellicle. Growth along the puncture-line is moderate.

The red color appears first about the top of the puncture-line, and gradually deepens in hue as it spreads through the agar mass. It is often several days before the red color is markedly developed in the agar. At 37° C. the growth is much retarded.

Glycerine agar tubes show the same characters as agar.

Gelatine Tubes.—A thin yellowish pellicle at first spreads from the puncture and becomes more or less cup-shaped. The growth along the puncture line is slight and diffuse. The gelatine is slowly fluidified, the fluid gradually assuming a rose-red color, as does the zone of solid gelatine about it.

When the fluidification is advanced, a yellow pellicle floats at the surface or sinks in a yellow mass to the bottom of the fluid.

Beef-tea becomes turbid at first, then reddish, with a sediment.

Blood Serum.—Growth similar to that on Agar.

Potatoes.—The growth is moderately rapid, forming a thick, irregular, raised greenish-yellow mass, which gradually becomes darker in color.

Subcutaneous inoculation in rabbits and white mice, even of considerable quantities, produces no appreciable effect.

Remarks.—There is considerable variation in the rapidity of growth and color-producing power in the different specimens of this bacillus which I have found. Its vigor seems to suffer somewhat under prolonged cultivation.

Cilia on Bacteria.—DR. JOHN S. ELY presented some microscope-slides showing cilia on bacteria, and made the following remarks: Great mobility has long been known to characterize many of the bacteria. From the first this was thought to be due to the activity of cilia on the ends of the bacteria, and in a few large species the truth of this was early demonstrated, but the vast majority of the mobile bacteria have until very recently baffled all attempts to discover their minute locomotive organs, and we have been obliged to infer their existence, without, however, being able to prove it. A new method of staining, introduced by Loeffler, makes the cilia easily visible. Loeffler very ingeniously hit upon the idea of intensifying the coloring power of his dyes by the use of mordants. The mordant recommended is an ink prepared by mixing a solution of tannin, ferrous sulphate, and infusion of logwood. To 10 c.c. of a twenty per cent. aqueous solution of tannin, an aqueous solution of ferrous sulphate is added drop by drop until a violet-black color is produced; then 3 or 4 c.c. of an infusion of logwood (1 part logwood, 8 parts water) are added, and finally 5 c.c. of a five per cent. solution of carbolic acid, to render the solution more permanent. This then is the mordant.

The stain is prepared by dissolving 4 or 5 grammes of the dye to be used, preferably fuchsin, in 100 c.c. of a saturated solution of aniline oil in water, to which 1 c.c. of a one per cent. solution of sodium hydrate has been added. This solution is quite permanent, but must be filtered before using.

Having now both mordant and stain, we proceed to employ them according to the following method: The material to be examined is dried on a cover-glass, and fixed by passing through the flame in the usual way. A few drops of the mordant are then added, and gently heated until steam begins to rise. The mordant is then carefully washed off with distilled water, and the stain is added, and heat applied as before. After a few moments the specimen is again washed, and is then ready for examination.

By this method Loeffler has succeeded in staining cilia on all the true spirals, on the comma bacilli of Koch, and of Finkler and Prior, on the mobile micrococcus recently described by Ali Cohen, and on a large number of mobile bacilli. The typhoid bacillus, however, resisted all attempts to stain its cilia. The stain is also well adapted to the staining of micro-organisms in tissues, but is then employed without the mordant.

The drawback to the general use of this method is the intensity with which all albuminous material is stained, often obscuring the bacteria when much is present. To avoid this, bacteria taken from bouillon cultures or from gelatine tubes should be first mixed with a few drops of distilled water to dilute the albuminous bodies present, and a small drop of this then taken for examination.

The specimen which I have is a mixture of many species of bacteria which grew in a hay infusion. There are many bacilli of various sizes, and besides these there are many spirals belonging to the species spirillum undula. On the ends of these may be seen cilia, sometimes single, sometimes in small bunches of five or six. Seeing these it is easy to account for the rapid motion of this spiral through the water of the hay infusion. Many of the bacilli in the specimen also show cilia, but these are much smaller and more difficult to see. While the cilia in the spirillum are straight, in most of the bacilli they are wavy.

As is but natural, very high powers of the microscope are necessary to render these minute structures visible. The specimen which you are examining is magnified one thousand diameters.

Tuberculosis of the Kidney.—DR. H. M. BIGGS presented some specimens with the following history: The

patient was admitted to the Charity Hospital, suffering apparently from gastritis. Examination of the urine at that time showed a small quantity of albumin, but this disappeared later. After having recovered from the gastritis he was found to be still very weak and was on that account retained in the hospital. After a while he was seized with intense headaches, for which he could get no relief, gradually sank, and finally died comatose. At the autopsy acute miliary tuberculosis was found, involving especially the lungs and brain, though a few miliary tubercles were seen in other organs of the body. There was absolutely no trace of any old tuberculous process in the lungs, but there was a perfectly characteristic tuberculous process going on in the left kidney, in which were found some cheesy masses, and destruction of the organ had occurred. The ureter on this side had also apparently been destroyed. The other kidney, the bladder, and other portions of the genito-urinary tract were apparently normal. One bronchial gland was found to be cheesy and calcareous. The case was interesting, especially because of the localization of the process in the genito-urinary tract and of the secondary development of tuberculosis in the lungs. The speaker thought that perhaps years ago this man might have had a very slight tuberculous trouble in the lung from which the infection in the kidney took place. Then, during his stay in the hospital, this last process gave rise to general infection, and acute miliary tuberculosis occurred.

Acute Miliary Tuberculosis of the Peritoneum.—Dr. Biggs showed a second specimen of acute miliary tubercular peritonitis, removed from the body of a woman, who had been admitted to hospital for delirium tremens. It was thought that death might have resulted from a rupture caused by intestinal ulcers, but nothing of the kind was found at the autopsy. There was no tuberculous process found in any other part of the body except one small calcareous nodule, perhaps one-third centimetre in diameter in the lung. There was a very recent acute general miliary tuberculosis of the peritoneum. The speaker did not believe that primary tuberculosis of the peritoneum ever occurred; yet, he said, it was very hard to persuade one's self that the disease could follow such a very small lesion in the lung.

Pancreatic Hemorrhage.—A third specimen shown was one of pancreatic hemorrhage. It had been removed from the body of an unknown man, who had gone into a saloon and taken a few glasses of beer, then went outside and fell down on the sidewalk dead. At the time the autopsy was made there was considerable decomposition present, and nothing could be found except a hemorrhage around the pancreas and a number of minute hemorrhages within the organ. Not much could be determined concerning the changes in the pancreas, because of the degree of decomposition present. The case was one of sudden death, due to pancreatic hemorrhage.

Aneurism of the Basilar Artery.—This specimen was obtained at an autopsy made with Deputy Coroner Jenkins. The patient was a young man, thirty-one years of age, apparently in perfect health, who went to his work one morning as well as usual. After working for about half an hour he complained to the foreman of severe headache and said he would have to stop. He went down to the lower floor of the house in which he was working, lay on the floor, and died almost immediately. At the autopsy there was found a large hemorrhage at the base and over the convexity of the cerebellum. On injection of the vessels of the base there was found a small aneurism at the side of the basilar artery, just before its bifurcation. The case was interesting because of the rarity of these aneurisms in young persons. Some time ago Dr. Biggs saw another case, with a very similar history, in which the same lesion was found at the autopsy. There was absolutely nothing else in either case to cause death. There was nothing to account for the occurrence of the aneurism, and the speaker was inclined to think that it was due to a congenital weakness of the vessel.

Secondary Adeno-Carcinoma of the Lung. — Dr. Frank W. Jackson presented a specimen of this lesion, with the following history:

The patient was a man, thirty-two years of age. He was admitted to the Roosevelt Hospital last July, without a definite diagnosis. For two months he had suffered from dyspeptic symptoms, loss of flesh and strength, night-sweats, and, latterly, marked dyspnœa. He also had pain in his abdomen when he moved. He considered that he had been in perfect health up to two months before, but it was found that his right testicle had been removed one year before. It was enlarged, but he did not know the nature of the enlargement. Some years before he had been operated upon for fistula in ano. There was no other history of previous illness, and his family history was good.

When admitted to the hospital it was evident that he was very sick; he was emaciated and anæmic. His dyspnœa was evident, and he had a slight cough. He was under observation for ten days, during which time he simply grew weaker. He had much dyspnœa, and from time to time expectorated a peculiarly viscid, jelly-like material of a brick-red color. He had hardly any rise of temperature.

His physical signs were interesting. There was moderate dulness over the bases of the lungs behind, the voice and breathing was found to be diminished over the whole chest, and crepitant and subcrepitant râles were heard all over both lungs. There was a large, hard, tender gland just above the left clavicle, and extending down beneath it. In the abdomen there was felt a hard cylindrical mass, just above the umbilicus, lying transversely across the vertebral column and apparently intimately attached to it. The vertebral bodies seemed very prominent, and the tumor seemed to be of the same consistency with the vertebræ. The difficulties of diagnosis were apparent. He looked like a man with phthisis, and his history of fistula in ano, enlarged testicle, and night-sweats pointed in that direction, while the physical signs in his lung were such as might readily go with chronic miliary tuberculosis. He had, however, no temperature, his cough was not severe, and his expectoration was from time to time peculiar in its brick-red color and gelatinous consistency.

Then there was the tumor in the abdomen to be accounted for. Was it a retroperitoneal growth, and was the enlargement of the testicle of a cancerous nature? Or were there phthisis and carcinosis combined? Some light was thrown upon this after a few days, when it was learned that the enlarged testicle had been examined after removal and found to be carcinoma.

The autopsy showed general carcinosis. There was a very large mass lying upon the vertebral column, and extending from the diaphragm into the true pelvis, involving the retroperitoneal glands and including portions of the intestines and the tissues about the kidneys. This was what I had mistaken for the spinal column itself, and the cylindrical tumor was simply a prominent nodule. Both lungs were infiltrated with cancerous nodules, the pleuræ were adherent, and there was a little bloody fluid in the pleural cavities. There was no phthisis.

The microscopic examination of both the growths in the lungs and in the abdomen show these to be adeno-carcinoma.

Fracture of the Skull.—Dr. H. J. Boldt exhibited a patient who had sustained a fracture of the skull from the kick of a horse. The accident occurred last July. The skull was crushed, and on putting the pieces together subsequently, those from the inner table were found to cover an area of something over two inches in diameter, and those from the outer table one of about one inch. The bone was in fourteen fragments, embedded in the dura mater and in the substance of the brain. Considerable oozing of brain tissue took place for some days after the injury. The pieces of bone were jagged, and some were extracted with considerable difficulty. All foreign mat-

ter which could be detected was removed, among other things a piece of a felt hat. There was very profuse bleeding from the nose and ear. There was paralysis of the left side of the face and left upper extremity, but this disappeared in the course of a few weeks, and at present there is remaining only a numbness of three fingers. A piece of the scalp was cut out after the foreign bodies had been removed, in order to give free discharge to any products that might be formed. In all about ten grammes of brain-substance oozed away, after which the scalp was raised and brought together by wire sutures. Dr. Boldt looked upon the hemorrhage as the result of a wound of the dura mater, for he had never seen bleeding from the ear in a case of simple fracture of the vertex without injury to the base. In reply to a question whether there might not have been a fracture of the base, he thought that there was none, for there had been no symptoms of such a condition. The man had been unconscious for about half an hour only.

Dr. Biggs said that it was not very rare to meet with cases of fracture of the base, in which there might be considerable hemorrhage, where the patients remained conscious for some time after the receipt of the injury, or might even not lose consciousness at all, in case the hemorrhage did not continue very long. Not so very long ago he had seen a man who had fallen from his truck, but at first gave no symptoms of any injury whatever. On the following day when he went to get his truck he seemed to be ill, and the foreman told him not to try to drive it that day. The man turned away, walked off the end of a pier, and was drowned. At the autopsy there was found a very extensive fracture of the base of the skull.

Dr. Van Gieson said that it would be interesting to watch this case pretty closely to see whether any symptoms of insanity would develop subsequently. The oozing of brain-matter was from the frontal lobes, and in two or three cases of this kind seen recently a peculiar form of scoffing or mocking insanity had followed the injury.

Fibroid Tumor of the Uterus.—Dr. Boldt then presented a specimen of fibroid tumor of the uterus which he had removed by the combined method. The reason why an operation was performed was that the pains from which the patient suffered could not be relieved in any way except by the continued use of morphine. The abdomen was opened and a ligature placed around the pedicle of the tumor, and the latter was then cut off above the ligature. After this the uterus was removed by vaginal hysterectomy. The speaker much preferred this combined method, believing it to be safer, as it removed the danger of infection from the stump.

The Society then went into executive session.

Heart-failure Cells.—In a recent article in the *Deutsches Archiv für klin. Med.* (October, 1889), Professor Hoffmann calls attention to the significance, from a clinical stand-point, of certain cells, to which he has given the above name, occurring in the sputum in cases of mitral disease, myocarditis, and pericarditis. These cells are distinguished by their size, more or less oval form, and beautiful balloon-shaped nucleus, but more especially by containing yellow, yellowish-brown, or even black pigment. They resemble in all points the desquamated epithelium of the alveoli, and are characterized by their pigment shading yellow to brown. Hoffmann regards the "heart-failure cells" as desquamated alveolar epithelium, and considers their presence in the expectoration as a sign that brown induration of the lung is present. Professor Sommerhardt refers their origin to proliferation of alveolar epithelial cells, which swell up and absorb the red blood-corpuscles extravasated into the lumen of the alveoli, becoming ultimately pigmented by the alteration of the corpuscular coloring matter. Hoffmann maintains, however, that in the lung in heart-failure these cells are derived from those under the epithelial covering, and obtain their pigment partly by diapedesis, partly by capillary hemorrhages into the lung-tissue.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE CURABILITY AND PREVENTABILITY OF PHTHISIS—ANALOGIES BETWEEN PHTHISIS AND LEPROSY—THE DESIRABILITY OF OPERATING FOR FISTULA IN PHTHISICAL PATIENTS—THE PROPOSED RECONSTRUCTION OF THE UNIVERSITY OF LONDON—SIR MORELL MACKENZIE'S LIBEL ACTIONS—SIR RICHARD OWEN.

London, March 5, 1890.

Dr. Arthur Ransome has selected "The Etiology and Prevention of Phthisis" as the subject of the Milroy Lectures now in course of delivery at the College of Physicians. In his first lecture he struck an encouraging note both as to the preventability and curability of phthisis. Various published observations were quoted in proof of the curability of phthisis; among these were some post-mortem statistics by Dr. Harris, of Manchester, who had found evidence of cured phthisis in thirty-nine per cent. of the necropsies at the Manchester Royal Infirmary. The returns of the Registrar-General showed that the mortality from the disease had largely diminished within the last thirty years. A similar improvement was observable in other countries, in proof of which Dr. Ransome quoted some statistics from Dr. Flint respecting phthisis in Massachusetts in 1857 and 1883. Referring to the bacillus of tubercle, Dr. Ransome said we must acknowledge that, whatever its mode of working, it was the specific cause of the disease. The constant association of the bacillus with the lesions of phthisis by no means excluded the possibility, often insisted on, of the secretion or production by the bacilli of certain unorganized morbific materials. Thus Neucki had separated a tetanizing poison from the bacilli, and Bonardi had demonstrated the presence in tuberculous sputum of certain organic bases which caused disturbance of the nervous system when introduced into rats and guinea-pigs. The bacillus could only be successfully cultivated within a very small range of temperature (between 86° and 107° F.) and required from two to three weeks for its development. It was very tenacious of life in sputum, the bacilli having been found virulent after one hundred and eighty-six days in sputum dried at ordinary temperatures; but there were observations tending to show that the bacillus has a short life within the body, and can only maintain its presence for any length of time by the appearance of new generations to fill the places of the dying! The mode in which the disease gained access to the body was noted long before Koch's time, the points of attack indicating that the infection came from without the body. The demonstration by Koch of an organism that must in most cases come from the air, and that could in this way penetrate the lungs, or enter the lymphatics by sores, only served to make assurance doubly sure.

An important result of Koch's discovery was that it placed tuberculosis undoubtedly among the class of microbic diseases. It had even been suggested that tubercle in its acute forms might become epidemic, but this view was hardly supported by facts. Tubercle could only be said to be allied to ordinary epidemic diseases in the sense that they were all parasitic disorders, and it might rather be regarded, like leprosy, as a type of an endemic disease. It by no means followed, however, that a disease need be contagious or epidemic because it was derived from without the body, and because it afterward travelled infectively along the channels of absorption or of circulation. Although infective it need not be infectious, and might be incapable of being conveyed directly from the body of one patient to that of another. Whether contagious or not, phthisis was sharply marked off from ordinary exanthematous disorders, not only by its specific micro-organism and its endemic habit, but also by its usually slow and creeping and irregular course, and by

the permanent growths and alteration of structure and destruction of tissue brought about by the bacillus. In searching for diseases kindred to tubercle we must look for those which were chronic, endemic, irregular in their course, and produced by the action of a micro-organism which had comparatively feeble power of irritation, but which, nevertheless, brought about inflammatory action tending to produce permanent changes and necrosis of the tissues, and travelling along the track of the lymphatics or in the current of the blood. Chronic glanders or farcy and actinomycosis had many features in common with tubercular disease. But the closest resemblances were to be found between tubercle, syphilis, and leprosy. The nearest approach to tubercle was to be found in leprosy. A micro-organism was closely associated with each disease, and the bacilli were so alike that the most accomplished bacteriologist could find little or no difference. Leprosy was like tubercle in its mode of attack, the entrance of the virus taking place at the most exposed parts of the body. Leprosy was very slow in its progress, and often with long intervals of latency, in this respect also resembling tubercle. The pathology of the two diseases was also strikingly similar. Both were distinctly endemic diseases and had been found in almost every country where human beings were collected together in any number. They were equally uninfluenced by climate and temperature. As phthisis is now, so leprosy was, formerly, endemic, not only in Asia and Africa, but also throughout Europe. Precisely the same controversy as was now waged with regard to phthisis was carried on as to the contagiousness of leprosy. It was not surprising that the question should be asked, as it was by Danielssen, whether leprosy was not itself a tuberculous disease? Dr. Ransome thought, however, that we could not allow ourselves to be led into affirming the identity of the two affections, as there were points of difference. The resemblances, however, which the bacillus of tubercle bore to the bacillus of leprosy might encourage us to hope that as this latter disease had been banished from our country, so also might tubercle ultimately disappear.

At the last meeting of the Medical Society a discussion took place on the desirability of operating for fistula in phthisical subjects. Mr. Herbert Allingham read a paper on the subject in which, while deprecating operations in cases of acute phthisis, he urged that in other cases operative treatment might prove useful if undertaken with proper care in the selection of time and place. Dr. Theodore Williams said he thought the existence of a discharge was rather beneficial than otherwise when it was not excessive in quantity; he would only advise operation in cases where the fistula gave rise to pain or worry. Mr. Marmaduke Sheild said that in order to secure healthy surfaces it was necessary to scrape the edges of the fistula when opened out; without this, healing would probably not take place. Precautions must also be taken to avoid the infection of the raw surfaces by tubercular matter. Mr. Harrison Cripps suggested dilatation of the narrowed external orifice of the fistula. He thought ether was not a desirable anæsthetic to use when operating on phthisical subjects, as it was calculated to light up dormant mischief in the lungs. Dr. Lowe recommended the immediate ligature of fistulæ. Mr. Taylor said he had only observed fistula as a complication of phthisis in one per cent. of the cases at Brompton Hospital. He thought these fistulæ seldom called for operation, but he would not be deterred from operating through any apprehension of inducing an increase in the lung symptoms. He had seen great benefit follow the removal of diseased limbs and joints, and he could not see why the same should not hold good in the case of fistulæ. Mr. Herbert Allingham, in replying, said he had seen marked improvement in the general condition follow operation in these cases.

The proposed reconstitution of the University of London is still in a somewhat nebulous condition. Fresh proposals continue to be put forward. The latest is, that (for the medical degrees) the examinations in arts and science should be conducted by the university as at present, but that the professional examinations of the Conjoint Examining Board (of the Colleges of Physicians and Surgeons) should be accepted in lieu of the present University examinations for the M.B. degree (Bachelor of Medicine). This implies a considerable lowering of the standard, especially if the system in vogue at the Conjoint Board (of allowing the examinations to be passed piecemeal) is continued, and is certain to be resisted strenuously by the present graduates.

Sir Morell Mackenzie's actions for libel against Mr. Steinkopf and *The Times* have terminated in his favor. Mr. Steinkopf has to pay fifteen hundred pounds as damages, and *The Times* has to pay two hundred and fifty pounds.

Sir Richard Owen, the eminent biologist, is dangerously ill.

OUR PARIS LETTER.

(From our Special Correspondent.)

TREATMENT OF PHTHISIS BY FRESH AIR—ELECTRICAL TREATMENT OF UTERINE FIBROMATA.

PARIS, March 7, 1890.

DR. DUJARDIN-BEAUMETZ read a report on a work by Dr. Nicaise, at the last meeting of the Academy of Medicine, in support of his candidateship as a member of that learned body, the subject of the work being the treatment of phthisis by the permanent aëration of the dwellings occupied by phthisical patients, particularly the rooms in which they sleep, and which is effected by keeping the windows constantly ajar, even in winter, measures being at the same time taken to prevent the patients being cold. Dr. Dettweiler has proved that phthisical patients can live in the open air. In the establishment at Falkenstein, of an altitude of one thousand three hundred and twelve feet, in the midst of woods, the phthisical patients pass their time in the open air in all seasons. The results obtained are very favorable. It is reckoned that there are twenty-five per cent. of absolute cures and twenty-seven per cent. of relative cures. Aëration is therefore very useful for tuberculous subjects. The researches of Dr. Nicaise have shown that at Carabaul a room with a southern aspect and a temperature which at sunset was 14° C., the window having been left wide open all day, could be maintained at about 10° C. during the night, even when the temperature of the exterior fell to 2° C., if the shutters were closed and if the window were left ajar about thirty or forty centimetres. In these conditions the aëration of the room, which was provided with a chimney, was perfect, and the temperature very acceptable provided that the patient is warmly covered in his bed. These points are very important. It is true that the air respired by tuberculous subjects does not contain bacilli, but with them, as with healthy subjects, the expired air contains irrespirable gases; and the researches of MM. Brown-Séquard and d'Arsonval have shown the existence of volatile products and of toxines. These substances are dangerous to breathe; they end by accumulating in the rooms where the aëration is imperfect; it is therefore very important to get rid of them. Dr. Dujardin Beaumetz thinks that it will be good practice to accustom phthisical patients gradually to live in an atmosphere properly renewed, which may be effected by certain arrangements which should not inconvenience the inmates. He adds that the non-success of specific medications in tuberculosis should engage us to ameliorate the hygiene of tuberculous subjects. To procure them proper aëration would be a real progress; but this must not be considered sufficient, and he concludes his report by insisting on the necessity of associating to the hygienic means a rational pharmaceutical treatment. The Academy voted the conclusions of the report, and thanks were addressed to Dr. Nicaise for his

important memoir, which will be deposited in the archives of the Academy.

With reference to the discussion that took place a short time ago at the Société de Chirurgie on the electrical treatment of uterine fibromata compared with the other methods, the system adopted by Dr. Apostoli was put in opposition to the modification introduced by Dr. Danion in conjunction with Dr. Lucas-Championnière. It will be recollected that Dr. Apostoli's method was severely criticised, particularly owing to the unnecessarily high intensities employed by this gynecologist, which are considered highly dangerous. Dr. Danion has again brought the subject to the notice of the Academy of Medicine, and the following are the conclusions of his very interesting paper: That the treatment of uterine fibromata by high intensities or by the galvanic puncture, as practised by Dr. Apostoli and his partisans, are subject to several objections: the method is painful, several accidents have been observed, and the application difficult and delicate. For several years the author sought a more simple method. He believes he has found one. He employs a tampon of amadou covered over with a leaf of India-rubber, except at one of its extremities, where a hole is made in the India-rubber about the size of half or one centimetre. The tampon is dipped into a solution of salt, and a platinum needle is passed through it and is thus connected with the battery. The tampon is then introduced into the vagina, exactly in the place chosen. A current of from 80 to 100 milliampères, and one might go to from 120 to 130 milliampères. It is necessary to reverse the current several times. Twenty of the most striking observations collated in the service of Dr. Lucas-Championnière permit the author to affirm the excellence of his method, in all cases, without its presenting the least danger. He remarks that, in this way, owing to the reversal of the current, the poles act indifferently. That with this method the presence of cysts or of lesions of the uterine annexes is never the occasion of the slightest accident. That the immediate effects on the symptoms are much more rapid than with the intra-uterine action and punctures, or even intra-cervical action, which appears due to the absence of all reaction, and that the reduction of size, incomparably more rapid and more considerable, which is observed, ought to be attributed to the reversals combined with the absence of all caustic action. That, with the exception of complications in the annexes, failures are absolutely exceptional. That it may be positively affirmed that the method of the electric tampon and of the reversed currents, by its simplicity, its power of action, and its absolute innocuousness, realizes a considerable progress. That in all cases, without exception, in which surgical intervention can be dispensed with, this method should be, preferably, employed in the treatment of uterine fibromata.

SOME OF THE SANITARY NEEDS OF JAPAN.

To the Editor of the Medical Record.

Sir: In a recent letter to Dr. Page, late chairman of the Academy Section on Practice, in alluding to an admirable article read before it by the late Dr. Cocks, entitled "Eye Symptoms as Aids to Diagnosis," I referred to two symptoms observed and verified in my Japanese experience, viz., inability of closure or adjustment of ciliary surfaces of the eyelids, from tubercular œdema; and deposition of brown pigment on the sclerotica—both initial symptoms of leprosy so constantly noted in the relation, as to be looked on with suspicion by the common people even.

The late Dr. Sato, of native hospital experience and reputation exceptionally and deservedly high, first brought them to my professional attention, and I, afterward, had frequent opportunity to verify his conclusion regarding them.

Dr. Page has suggested that I write you of these observations.

And here, let me refer briefly to your editorial in the issue of March 8th, entitled "The History of Modern Medicine in Japan."

The influence of European medicine through the Portuguese navigators, or Spanish Jesuits, was never lost to Japan, as stated by Dr. Nagayo. All knowledge of medicine in Japan, as in China, before the wisdom of publication even was perceived, being handed down, in a free-masonry of medicine, from preceptor or teacher to favorite pupils; the secrecy of medical knowledge being held inviolate.

After the expulsion or massacre of the Christians, for their attempt to subvert the power of the Mikado's religious dominion, their European knowledge remained to temper the old Chinese and Japanese system. I think the Holland or Dutch influence antedated the Portuguese; at any rate it preceded the date, 1750 A.D., to which Dr. Nagayo refers. At this date (1750) there were no "treaty-ports." Japan, after the expulsion of the Jesuits, was a closed kingdom, till re opened by Commodore Perry's advent.

In the schools of Tokio, at the time of my arrival in the country, German medical influence was in the ascendancy, French military teaching, and English engineering teaching, commanding respective supremacy.

The ability of Japanese medical men is greatly underrated by Europeans and Americans. They are of superior acumen as diagnosticians and therapeutists, but their surgical skill is not so able, for the reason that Japanese vocations do not result in many accidents. The surgery of Japan is not immediate but secondary to diseases, mostly of genito-urinary or venereal origin.

Diseases of the eye are manifold and wide-spread, the result of[1] frequent "sand-storms" from across the bays along the coast,' and from small-pox.

Virulent small-pox has been ever constant in Japan, but seemingly not as fatal as with us; as most all persons to be met on the streets and in public places are terribly pitted and scarred, showing recovery from severer confluent forms. The Japanese do not fear small-pox as we do. In 1874, during an epidemic in the city of Tokio, the streets and stores were full of walking cases; a confectioner waited on me personally, in one of the stores on the principal street ("Ginza") of Tokio, who had a delicious type of the disease, in its umbilical stage.

Eye surgery of Japan is very inferior. Many cataract extractions and iridectomies being incompetently per formed.

Blindness is abundant, from the three causes and their results, viz., small-pox, sand-storms, and incompetent treatment.

Influenza is common during the peculiar weather or meteorological conditions attending the earthquake season, just preceding the spring and fall exhilarating monsoons.

To-day medical teaching in Japan is wholly modern, and vast strides are being made to catch or surpass us. I cannot agree, however, with Dr. Nagayo, that it is reserved for his country "to unravel the truths of creation." It must first unravel problems belonging especially to his "Sanitary Bureau"—for example: 1. The supply of pure drinking-water through impervious pipes, to the people of Tokio, and the prevention of its contamination from public urinals and night-filth. 2. Medical supervision of its fish supply, which is brought to Tokio, in ship loads, and dumped in huge piles on uncovered wharves, exposed to sun and weather, poisonous and non-poisonous kinds mixed together, although afterward sorted. 3. Other disposition of its night-filth, than its carriage in buckets on men's shoulders, through the streets in daytime, to open boats moored in the canals, and to be scattered broadcast over its widely distributed rice-fields, with consequent poisoning of all the streams and drinking-wells in the whole country. 4. A mode of conveyance other than the man carriage, or "jinrickisha," thousands upon thousands of

[1] The Japanese are coast dwellers mainly.

which are used in Tokio alone, with resulting fatal heart disease in a few years, at the longest, to the poor men who earn a livelihood by running them. 5. Medical supervision or inspection of the vast system of public hot baths, to separate the diseased from the well, and for the more frequent renewal of the supply of water than is now done. The abolishment of the insidious charcoal stove from the houses of the Japanese, with its resulting poisoning by inhalation of carbonic acid gas. 6. Sanitary inspection of the sinking of wells for drinking-water in the crowded parts of the city and country, through a soil reeking with population filth.[1] 7. The filling up of the old central castle moats in Tokio (sixty miles in extent), now but swamp-pools of malarial infection and decaying lotus débris.

Until these sanitary improvements are instituted in Japan, there will be *no* "unravelling of the truths of creation."

Yours, very sincerely,

ALBERT S. ASHMEAD, M.D.,
Late Foreign Medical Director, Tokio-fu Hospital.

TOKIO, JAPAN.

IN FAVOR OF HOME PRODUCTION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The clinical study by H. H. Spiers, M.D., in your issue of the 22d ultimo, was very interesting to me. I hope to find more of such practical productions in your columns. Strike out a few of the long-winded articles, or compilations, with a thousand and one foot-note references, by eminent (?) specialists. I think writers are too prone to ape the foreign—let them mix in a little of the American. Yours, truly,

X., M.D.

MONTANA, March 4, 1890.

ADVERTISING THROUGH A CHARITY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Premising that I have not felt, in all the years I have been at work, the necessity for subscribing to any other journal than yours, I beg to say that "superfœtation" in your article on "—— Hospital Reports," page 275, just describes the situation. They are, indeed, only advertisements, ostensibly of the "Great Behemoth," but essentially and practically of those, and only in the interest of those, who had the fortune to cause themselves to be "called" to form its bone and marrow! The advertisements of the Johns Hopkins are on public sale in Baltimore continuously, and as anybody can purchase them, there can be no question but that they make the usual impression on those whom the selected few desire to reach, irrespective of the Code of Ethics as well as any other legitimate obligation they might or should have toward the brethren of their profession. Merchants and other business men are only too happy to have their "ads" noticed; but in the case of the Johns Hopkins University the public cheerfully pays all expenses, reads the "ads," and swallows them down as pure gospel, having no thought that possibly the surprising feats therein depicted, to which general attention had not previously been so pointedly called, might still be accomplished, or have been before, by many humbler medical men who owe their living to personal merit rather than to the tacit backing of a great name and corporation, and, perchance, with more satisfactory results. For my own part, I am so far away from the Hopkins Hospital that I have never seen it, and don't want to, but, in the absence of more positive knowledge, suppose it attends to its own business, as any honest person would, according to its own conscience, if it has any—if it has not, it is sure to cut a wide swath with one inevitable result.

Respectfully yours,

B. F. GROVE, M.D.

[1] All of the roads of the country are but part of a huge city, being crowded nearly as closely as the cities.

THE LATE DR. CHARLES McMILLAN.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I had hoped to see a more extended notice of Dr. Charles McMillan than a bare announcement of his death, and have waited for some of his army friends to do justice to an old comrade before attempting it myself.

Dr. McMillan was the son of a physician, and was born in Conesus, Livingston County, about 1824. His family and mine were pioneers in that lovely part of the country. I first knew him as a bright, manly boy at Temple Hill Academy, in Geneseo, and since then our friendship was unbroken. We became students of medicine about the same time, and graduated in New York in 1849; 1851 found us together in an office at No. 310 West Twenty-third Street. Dr. McMillan soon afterward removed to Fordham, and was there a busy practitioner when the war broke out in 1861. Some may yet remember the Twenty second Regiment, among the first to respond to the call of President Lincoln, as it marched splendidly down Broadway, with Dr. McMillan as its surgeon. At the close of the three months' volunteer service he was made brigade surgeon, and was attached to General Hunt's staff in the Peninsular campaign under McClellan.

I shall always remember his graphic description of the battle of Malvern Hill. He was at Chattanooga, and saw the battle above the clouds. Later on he was at Vicksburg a short time as Medical Director for General Grant, and held the same office for a longer period under General Sherman. I still have photographs of those then rising commanders, with the autograph of General Sherman, which Dr. McMillan brought to me when he came home on leave, before Vicksburg was taken. After the war he was Consul-General for Italy, and lived several years in Rome. Upon his return to his native land he took up his residence in Washington, and when he died was connected with the Pension Office.

His widow survives him in her home in Washington.

Yours, sincerely,

J. R. LEAMING, M.D.

NEW YORK, March 20, 1890.

ANTISEPTICS AND THE COUNTRY DOCTORS AGAIN.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: After five weeks of the worst railroad blockade ever known in this country, during which time there were no mails at all, my back numbers of the RECORD are before me. I find in your issue of January 18th, that I am brought up, or rather rounded up, by a gentleman who hails from the classic village of Oshkosh, Wis., who endeavors to prove my ignorance simply by echoing many things that have been said and written a thousand times before. I write from my personal experience chiefly, while the Oshkosh brother writes from his imagination. He says I claim "to voice the sentiments of the country doctors in general," which he denies. Since writing the article which called forth his reply, I have received letters from Indiana, Rhode Island, Maine, Wisconsin, Minnesota, and from other sections of the country, endorsing my opinions and congratulating me. Dr. Kemper, of Muncie, Ind., writes that he has attended nine hundred cases of obstetrics and has never used antiseptics in the strict sense of the term, and has only had three deaths. I would like to see better results than these anywhere. A gentleman from Maine writes me that the profession is insane on the subject. Another from Rhode Island writes me to keep on with the good work. These are only a few samples of the letters I have received. I also see that the article was reprinted in *Practice* almost entire. So much for the sentiment of the profession in the country. The fact that I have read the RECORD for thirteen years constantly is sufficient evidence that I take it for instruction and not for amusement, as

the brother infers. Of course, the skilful use of the curette can be acquired at Oshkosh better than in the country. To belittle a thing or ridicule it, is not argument. I know that many of the profession in the cities think they are much superior to the country doctor in skill and brains; however, let that pass. Anyone who reads the journals will remember occasionally to have seen the statement, "patient died with symptoms of sublimate poisoning," or carbolic acid poisoning, or iodoform poisoning, etc. Now, it is much more in the line of human nature to record successes than failures, and it is not too much to infer that, for every case of antiseptic poisoning that is recorded, there are one hundred cases that never see the light of day. No, there are no statistics of death from antiseptic poisoning kept. The statistics would be too painful to contemplate. My friend would like to know how many times I have obtained primary union in amputations of extremities. I think my first communication answers his question, but will state that in the last amputation I performed, union occurred primarily, with only a little serous discharge, which was odorless, and there was no inflammation or gaping of the wound nor constitutional disturbance whatever. It was an amputation through the upper third of the humerus for a railroad injury. I kept the flaps open until all oozing had ceased and the surfaces were covered with lymph, I then closed them and put in the sutures, and used carbolized vaseline as a dressing. Strict cleanliness was observed, both as to hands and instruments. In a town of two thousand people, a doctor does not have many capital operations to perform. I expect definite results when I amputate, if the condition of the patient is such as to warrant the expectation. I would like to ask the friend from Oshkosh how many times he has operated for osteomyelitis by the Shade or Senn method, and had complete recovery in a few weeks? I am afraid he has never operated by any method, and consequently, cannot judge from a personal experience whether it takes weeks or months to make a recovery. I am expected to class myself as a "back number," according to the ideas of this Oshkosh luminary; but I will leave that to the opinions of the readers of the RECORD.

It is indeed refreshing that no allusion has been made to the Tait "chestnut," as he calls the opinion of the great master of abdominal surgery. I am glad that this much of my article meets with his approbation, but I am compelled to give him a new "chestnut" to nibble on, and I hope he will not get the burr of it under his crupper, as he might kick then more than he does now. George G. Bantock (*Medical Analectic and Epitome* for January, 1890) reports a series of four hundred cases of ovariotomy performed by himself, and expresses the following opinions: Antiseptics are unequivocally denounced as being dangerous. Strict cleanliness is insisted upon. Plain water, not even boiled, is the only fluid used in the operation, and the abdominal cavity is perfectly cleaned out and kept so. His first series of 100 cases, performed with strict antisepsis, 19 deaths; 2d, 100 cases, Listerism being gradually abandoned, 14 deaths; 3d, 100 cases, plain water only was used, 8 deaths; 4th, 100 cases, water only, 4 deaths. In the Samaritan Free Hospital, the same operator did not lose one patient out of ninety cases operated on without antiseptics, during three years and a half, while during the same time the mortality under the Listerian method was twelve per cent. Now, I will make the assertion that not one doctor in five hundred uses the antiseptic system unless he is attached to some large hospital. It has been also proved that to kill microbes in the weakest antiseptic solutions compatible with the vitality of the living tissues, takes from one to six hours; how, then, is the irrigation of a wound for a few minutes with antiseptics going to have any effect, other than to irritate?

Echo cannot answer this question, but perhaps this son of Oshkosh can. In conclusion, Mr. Editor, I would like to ask why, if antiseptics are useless and dangerous to use in abdominal operations—the severest and most difficult ones in all surgery—why are they not equally useless and senseless in the medium and minor operations?

F. W. VAN DYKE, M.D.

GRANT'S PASS, ORE., March 1, 1890.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 22, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	10	5
Scarlet fever	68	12
Cerebro-spinal meningitis	2	0
Measles	163	11
Diphtheria	96	28
Small-pox	0	0
Varicella	10	0
Cholera	0	0

Neumann on Hereditary Syphilis.—From an elaborate study of this subject, based on 261 cases, Professor J. Neumann, of Vienna, has arrived at the following conclusions (*The London Medical Recorder*): 1. A syphilitic mother is capable in every stage of the disease of transmitting it to her offspring, no matter whether she has been infected before or after conception. 2. Syphilis acquired by the mother after conception sometimes passes to the fœtus, but this very rarely happens when the mother's infection has taken place in the last months of pregnancy. 3. If the mother be infected after conception, the father having been syphilitic at the time of procreation, the effect on the offspring is much more severe, the child either dying *in utero* or being born with syphilis. 4. In syphilis acquired by a mother after conception, the state of health of the father at the time of procreation being unknown, the situation is the same as when the syphilis is obviously post conceptional. 5. When infection and conception occur together, half the children die. At the same time it must be remarked that a large number of children remain free from syphilis, although that disease may have been in activity in both parents at the time of conception. 6. When infection precedes conception, the period at which the latter takes place is the first point for consideration. The longer the interval between infection and conception the more favorable is the prognosis as regards the offspring. An energetic mercurial course has always a good effect; for example, among the author's cases, even when infection and conception had occurred simultaneously, there were healthy children when the parents had undergone treatment by mercurial inunction. 7. The chances for escape for the offspring are greatest when the mother has acquired syphilis during pregnancy, especially during the later months, and the father was healthy at the time of procreation. On the other hand, the chances of escape are least when conception and infection have occurred at the same time, or when the father suffers from recent syphilis at the time of procreation. Of the fatal cases observed by the author, most come under the headings of "Conception and infection simultaneous," and "Post-conceptional from a syphilitic father." 8. The dangers of paternal syphilis are well shown by certain cases in which the father was syphilitic at the time of procreation, the mother only having become infected after conception, and in which a macerated fœtus was born prematurely. This is contrary to what was taught by Boeck and Oewre, who were of opinion that the child of a syphilitic father is healthy. 9. The observations to the effect that mothers infected during the later months of pregnancy usually bear healthy children seem to show that the practice of

bringing on premature labor, recommended by Oewre and other authors, is not only unnecessary but detrimental. 10. That tertiary syphilis does not cause sterility in a woman is a fact that need only be mentioned. 11. Experience has shown that a protracted course of mercurial treatment, as recommended by Hutchinson, has a favorable effect on the health of the offspring. 12. The author cannot, however, agree with Hutchinson that it is unimportant as regards the intensity of the disease in the child whether one or both of the parents were syphilitic at the time of conception. Out of forty-one of the author's cases, in which conception and infection took place at the same time, only fourteen children were healthy.

The Sweat of Phthisical Patients contains tubercle bacilli and is contagious, according to the experiments of Dr. Eugenio de' Mattei. The bacilli are not exuded from the skin, however, but get upon the skin and so into the sweat, from dried sputum.

Influenza or Dengue.—After discussing the question of the identity of influenza with dengue, Proust sums up his remarks by saying that the epidemic of influenza prevailing at Paris does not present all the classic and ordinary characters of the grippe as they are usually observed; but that it does not, on the other hand, exhibit the *ensemble* of symptoms of dengue as described by physicians who see it in the countries where it prevails. The epidemic is certainly the same affection which now exists at St. Petersburg, Berlin, Rome, and Madrid. It is remarkable for the short duration, as well as for the benignity of the symptoms attending it. In discussing this question, which has been repeatedly raised regarding the present epidemic, Limarkis, who, living in Constantinople, has had ample opportunities to see both diseases, gives a series of differential symptoms. These, arranged in tabular form, are as follows:

	Dengue.	Influenza.
Localization:	Hot countries.	All climates.
Duration of an epidemic:	Three to five months.	About one and a half month.
Spread:	Slowly, from small foci.	Rapidly, attacking large districts simultaneously.
Commencement of the disease:	Always sudden.	Almost always sudden.
Fever:	Always very high.	Not always very high.
Nervous system:	Prostration, pain in the head and limbs.	The same.
Larynx and trachea:	Seldom attacked.	Always attacked.
Dyspnœa:	Never.	Common.
Gastric symptoms:	Always; violent, persistent.	May be absent.
Eruption:	Always; beginning in the face, descending, erythematous, ending in desquamation.	Rare, irregular.
Headache:	Sensation of external pressure; iron hoop.	Violent, internal, often neuralgic pain.
Complications:	Rare; of heart, liver, and kidneys.	Common; bronchioles and lungs.
Convalescence:	Very slow.	Usually rapid.
Prognosis:	Always favorable.	Often occurs in malignant forms.
Attacking animals:	Dogs, cats.	Horses.

Still further proof that influenza is not a form of dengue modified by climate is the fact that the former occurs in hot countries in exactly the same form as in Northern Europe, and that the two diseases have just appeared in Constantinople, the one shortly after the other.—*The American Journal of the Medical Sciences*, March, 1890.

Some Startling Professional Statistics.—According to the Berlin correspondent of the *Medical Press* it will be remembered that last year the *Deutscher Aerztebund* felt it to be its duty to warn the guardians of young men, through the gymnasiums, against entering the profession of medicine, the state of overcrowding being so great as to insure disastrous consequences. Such a warning has not yet had time to make itself felt statistically, and again a considerable increase in the ranks of the profession is to be recorded. At the end of 1888 the number reached a total of 17,690, while the close of 1889 saw it swollen to 18,467, showing an increase of 4.4 per cent. The distribution of these is a matter of some interest. This follows not only density of population, but also the social condition. Where the population is better off a larger proportion of medical men is supported. Numerous calculations have been made with the figures given, one giving the number per 1,000 of inhabitants in the various provinces and departments, and another the number per 100 square kilometres, and so on. In the whole empire the number per 10,000 of population is 3.92, against 3.60 in 1887. In Hamburg the number is 6.61 per 10,000; in Lubeck, 5.91; in Mecklenburg-Strelitz, 5.90; in Bremen, 4.47; in Hessen, 4.93; in Brunswick, 4.80; in Baden, 4.77; in Saxony, 4.18; in Bavaria, 4.12; in Prussia, 3.74; in Alsace-Lorraine, 3.67; in Würtemberg, 3.39; and in Berlin, 9.32. Among the German provinces Hesse-Nassau heads the list with 3.44 per 10,000, then comes Schleswig-Holstein with 4.28; Hanover with 4.15; Rhineland, 3.88; Saxony, 3.71; Westphalia, 3.50; Brandenburg, 3.21; Pomerania, 3.08; Silesia, 3.02; West Prussia, 2.35; East Prussia, 2.32; and Posen with 2.20 per 10,000 of population. As regards Regierungsbezirken or Government districts, Wiesbaden stands highest with 6.78, and Gumbinnen, in East Prussia, the lowest with 1.59. During the year the mortality among medical men was 2 per cent., as against 2.68 per cent. the year before, being somewhat higher in country districts than in towns, as shown by the fact that among 3,707 medical men practising in forty-six of the larger cities of Germany there were 60 deaths, equal to 1.6 per cent. As medical men in commencing practice, or settling down, are obliged to notify such a fact to the authorities it is not so difficult to follow their movements as in some places. In Prussia there are 10,667 medical men, of whom 800 changed their residences during the year 1889; 150 of them performed the operation twice. In Berlin 113 medical men settled in practice during the year, of whom 17 did not meet with sufficient success to warrant their remaining. In Breslau 29 settled down, and 7 of them left again before the year was out; 13 settled in Cologne, 10 of whom were remaining at the end of the year. In Magdeburg one practitioner died, and eight others came in his place, and were still persevering at the close of the year. It may interest the curious to learn that in Prussia, during the year, three professors were nominated in the medical faculty, five Geheime Medizinalräthe (Privy Medical Councillors), twenty-one Geh. Sanitätsräthe (Privy Sanitary Councillors), and seventy-seven Sanitätsräthe (Sanitary Councillors). The Councillors and Privy Councillors are in the great majority of instances mere empty titles, possibly analogous to your own Q. C., but not the less object of desire on that account.

Universities of the World.—Norway has 1 university, 46 professors and 880 students; France has 1 university, 180 professors and 9,300 students; Belgium has 4 universities, 88 professors and 2,400 students; Holland has 4 universities, 80 professors and 1,600 students; Portugal has 1 university, 40 professors and 1,300 students; Italy has 17 universities, 600 professors and 11,140 students; Sweden has 2 universities, 173 professors and 1,010 students; Switzerland has 3 universities, 90 professors and 2,000 students; Russia has 8 universities, 582 professors and 6,900 students; Denmark has 1 university, 40 professors and 1,400 students; Austria has 10 universities, 1,810 professors and 13,600 students; Spain has 10 universities, 380 professors and 16,200 students; Germany has 21 universities, 1,020 professors and 25,084 students; the United States of America has 360 universities, 4,240 professors and 69,400 students; Great Britain has 11 universities, 334 professors and 13,400 students.

The Cost of Bodies.—A Philadelphia paper states that dead bodies can be bought in that city for five dollars apiece, delivered.

MALIGNANT DISEASE OF THE CORPOREAL ENDOMETRIUM.[1]

BY HENRY C. COE, M.D.,

SURGEON TO THE NEW YORK CANCER HOSPITAL.

I WOULD offer as an apology for introducing a subject which may not be of general interest to the profession the fact that it is one which has occupied my attention considerably of late, for the reason that I have treated no less than five cases of this somewhat rare affection at the Cancer Hospital during the past six months, and therefore feel as if I could discuss its clinical features by the light of personal experience. I have said that primary malignant disease of the body of the uterus was "somewhat rare," yet, when we remember that no uterine affection is so uncommon that any general practitioner, however limited his opportunities for gynecological work, may not encounter it, and that its early recognition is a matter of vital importance to the patient, it is evident that even this special subject may claim your earnest consideration for a few minutes. It is my purpose to present a brief *résumé* of our existing clinical knowledge with regard to this condition, rather than to enter upon a discussion of its etiology and pathological anatomy.

Under malignant disease of the corporeal endometrium I would include in their relative order of frequency carcinoma, sarcoma, and adenoma. As to the frequency with which they occur I doubt if we can yet speak positively, because of the unfortunate negligence of those who are in a position to add to the statistics. The off-hand statements of specialists who discuss these questions before medical societies are of little or no value from a scientific standpoint, since they are seldom supported by actual anatomical evidence. A man may say, as you read in well-known text-books which I might mention, "I have not found that carcinoma of the body of the uterus is so rare as is generally stated," but this is only his individual opinion, which has little weight in the accurate balance of the statistician. Witness the imperfect data given by such authorities as Barnes and Thomas with regard to the occurrence of uterine cancer, and the discrepancy between the statements of Sir James Simpson that he had met with 1 case of primary carcinoma of the corpus uteri to 15 cases of carcinoma of the cervix, and those of Schroeder, who observed only 1 in 53, and Zukits 1 in 420 (!). Again, Courty stated that he had seen "some 20 cases," when, a year before, Gusserow had only been able to collect from all sources 80 authentic ones, and but 1 had been observed in the Vienna hospital out of 429 cases of uterine cancer. It is useless to try to reconcile these conflicting statements. We are compelled to believe that in many instances the diagnosis was based on clinical symptoms alone, which are often misleading. Recent writers are more careful, so that we can depend more upon their statistics. Thus Williams, in his "Harveian Lectures" for 1886, throws out all cases in which the diagnosis was not confirmed by an actual examination, not of scrapings alone, but of the entire uterus after removal, and of these genuine ones he has seen only 7. Ruge and Veit have examined 21 undoubted specimens of primary cancer of the body. Even Gusserow's latest collection of 122 cases is open to suspicion, as he himself admits.

When we come to the question of the frequency of sarcoma of the corporeal endometrium, statistics are wholly unreliable, since in many such cases the diagnosis is based upon an examination of scrapings alone, or, more often, simply on the gross inspection of material curetted from the uterine cavity. I endeavored to gain some idea of the relative frequency of these two forms of malignant disease by reviewing the entire records of the Woman's Hospital since its foundation, but no definite information was obtained. Among 9,000 patients, 15 cases of carcinoma and 18 of sarcoma of the body of the uterus are recorded, with 23 in which the form of malignant disease is not specified. Now, I know that since my first connection with the hospital, in 1881, the diagnosis was rarely confirmed by an examination of the growth *in situ*. Thus, in a single year eight cases of sarcoma were reported, the diagnosis in every instance being based on the clinical symptoms and microscopical examination of the scrapings. It is extremely difficult to deduce any facts of positive scientific value from hospital statistics, because the records are necessarily uneven by reason of the wide variations in accuracy of observation and statement among the men who make them. That there is little attempt made to differentiate the above-mentioned forms of malignant disease is evident from the following quotation from a recent work on gynecology: "When the body of the uterus is primarily affected with cancer, it is generally in one of two forms, true carcinoma, or, more frequently still, sarcoma, either round-celled or spindle-celled." In spite of the statements of clinical writers, sarcoma of the uterus (and, above all, diffuse round-celled sarcoma of the corporeal endometrium, which we are now considering) is very rare—"so rare," says a conservative writer, "that every carefully observed case which has been authenticated by microscopic examination should be placed on record." Winckel tells us that with his extended opportunities for clinical observation he sought for a case for eight years before he found one, and subsequently has seen but four. Gusserow, up to 1886, had collected only seventy-four cases, including both varieties of sarcoma. These data, furnished by accurate observers, are calculated to make us suspicious of the loose statements of those who would have us believe that they meet with half a dozen cases of sarcoma annually. Not so Goodell; this conscientious teacher admits that he has seen only three cases in which the diagnosis was verified by the microscope. I have certainly examined only two sarcomatous uteri that were removed per vaginam, though I have several times examined scrapings of the endometrium, which in sections presented the microscopical appearances of round-celled sarcoma, the patient having at the same time the symptoms ordinarily referred to the presence of that disease; but no radical operation was done, and the patient subsequently passed from under my observation without my having been able to confirm the diagnosis.

When we come to the third form of malignant disease of the corpus uteri, diffuse recurrent adenoma (*adenoma diffusum malignum*), our statistics are still more imperfect. Several isolated cases are referred to by Winckel, Gusserow, and Schroeder, but no attempt has been made to collect all that have been reported. Few American writers describe the disease, Thomas and Goodell having each met with two cases, in none of which, however, was

[1] Read before the New York State Medical Society, February 3, 1890.

a section of the growth made *in situ*. Mann describes the microscopical appearances in a case of what he terms "villous degeneration of the uterine mucous membrane," the specimen having been removed *post mortem* from a patient of Lusk's. Bertolet (quoted by Goodell) reports a similar case, and Mathews Duncan is credited with two. To these I can add four undoubted cases (two of my own) in all of which I had an opportunity to examine the uterus after it had been removed during life. The specimens were exhibited at the New York Obstetrical Society, two of them on the same evening.

I present this hasty review of the literature of the subject, in order to emphasize the fact that primary malignant disease of the corpus uteri is unquestionably rare, so rare indeed that no careful man will decide that he has a case until he has weighed all the evidence and has had his diagnosis absolutely confirmed by the pathologist, and that only after the latter has examined the entire uterus. The question of etiology need not detain us, for the reason that we know nothing about it. It may be of interest to call attention to the fact that in between twenty and thirty per cent. of the reported cases of malignant disease of the corpus uteri, the patients were sterile, which seems to show that pregnancy and parturition are not active etiological factors. Sarcoma is more common before, and carcinoma and adenoma after, the menopause. In my experience age is an uncertain element in the diagnosis of cancer; the climacteric is a far more important index of the patient's liability to malignant disease.

With the pathological anatomy of these growths you are already sufficiently familiar. Primary cancer of the endometrium has until lately been thought to assume almost invariably the form of epithelioma, which develops from the superficial epithelium, and occurs either as a diffuse infiltration of the endometrium or as circumscribed polypoid masses. More recently, pathologists are coming to the conclusion that malignant adenoma, or its further stage, adeno-carcinoma, which develops from the glandular epithelium, occurs more commonly than was formerly supposed. Into the much-vexed question of the differential diagnosis between simple adenoma and so-called adeno-carcinoma, I shall not enter here, as we are more concerned with the clinical side of the matter. It may be stated that the practical rule will be found to be a good one—to regard as histologically malignant an adenoma which infiltrates the submucous muscular layer, and in sections of which we find, beside the usual glands, nests of epithelial cells showing a well-marked alveolar arrangement.

The gross appearances of primary epithelioma of the corporeal endometrium, as I have observed them, vary according to the stage of the growth. The mucous membrane may be studded with small cauliflower masses, varying in size from a pin's-head to a marble, or there may be a general infiltration of the mucous and submucous layers with a soft, gelatinous material, or, finally, necrotic changes may have produced a general sloughing surface, in and around which are few or no traces of the original growth. Diffuse round-celled sarcoma (we exclude, of course, the interstitial variety) is apt to be softer and more brain-like in character, presents an opaque, grayish—rather a whitish—gelatinoid appearance, is more vascular, infiltrates the deeper layers more slowly than epithelioma, and necrotic changes occur later. But it is impossible to make a macroscopic differentiation between these two varieties of malignant disease; in fact, we often find on microscopical examination that the same specimen presents the characteristic appearances of both, so that Klebs affirms that most of these growths should be described as carcino-sarcoma. The most exquisite specimen of diffuse malignant adenoma of the endometrium which I have seen, or of which I have read, was a uterus removed by Dr. W. Gill Wylie by suprapubic amputation. My description of this will be found in the "Transactions of the New York Obstetrical Society for 1886." The entire corporeal endometrium was transformed into a thick villous growth, which invaded the muscular layer, but showed no evidences of ulceration. It was clearly malignant, clinically, though microscopically it was a pure adenoma, corresponding exactly with Schroeder's description. In my first case the growth was confined to the posterior wall of the uterus, which was generally softened and infiltrated, in fact, I considered that it had already crossed the boundary line and was to be regarded as an adeno-carcinoma; in the second, as also in Dr. Bache Emmet's case, it was strictly circumscribed, being confined to an area the size of half a dollar, and had only begun to invade the submucous tissue. The two latter were described by the pathologist as "papillary adenoma," but undoubtedly belong under the same category as the first two specimens.

I shall not dwell upon the microscopical appearance of these growths, though allusion will be made to them subsequently in discussing the question of diagnosis. For reliable information on this subject I refer you to the paper by Louis Heitzmann, in the *American Journal of Obstetrics* for September, 1887.

Considering how much has been written regarding the symptoms and diagnosis of malignant disease of the interior of the uterus, it would seem as if we possessed sufficiently explicit directions for recognizing even the most doubtful case. In point of fact there is nothing in the whole range of pelvic diagnosis which is more difficult. The classical symptoms of carcinoma and sarcoma of the corpus uteri are pain, hemorrhage, and fetid discharge. The most recent American treatise on diseases of women (Skene's) contains the following misleading statement: "Pain occurs early, and is severe and paroxysmal, sometimes remaining at its pitch for two hours. Intense menorrhagia is soon accompanied by a discharge which is profuse, watery, and fetid. . . . The vital forces are early greatly depreciated, and marked constitutional disturbance is a prominent early symptom of cancer of the corpus." In contrast with this, note the conservative remarks of that able pelvic pathologist, Winckel: "The chief symptoms are hemorrhage, pain, offensive discharge, and emaciation, as in carcinoma of the cervix, though they manifest themselves in a characteristic manner. In the first place, while the discharge of blood is very frequent, it is inconsiderable, and is only a mucus tinged with blood; profuse hemorrhages are rare, a fact which has an obvious explanation in the vascular arrangement of the inner layer of the uterus. The pains, too, are not very severe, even when the disease has made great progress." I do not think that those who have carefully observed several examples of this disease will have any difficulty in deciding which of these strongly contrasted statements is based upon facts. You will see, when I review my cases, that Skene's description fits only such as are in an advanced stage, when the signs are unmistakable. Anybody can recognize a typical case—medical or surgical—but as concerns malignant disease, the recognition often comes too late. It is not enough that the gynecologist should be able to detect its existence at a stage when it is still possible to entirely remove it; the general practitioner is the one who is directly responsible for the vast majority of those mournful inoperable cases, which are referred to us at a time when we can only pronounce them hopeless. I discussed this question thoroughly in a paper on "Early Recognition of Cancer of the Cervix Uteri," which was read by title at the meeting of this Society a year ago, so that I shall not enter upon it here. The point which I wish to make is this: As general practitioners it is your duty to investigate thoroughly every case in which the symptoms are only suspicious, and not to be satisfied until you have, either in person or with the aid of a specialist, absolutely excluded malignant disease.

What are these suspicious symptoms? Not severe, lancinating pain, because that is a later symptom, due either to the exposure of nerve-endings in the deeper layers through ulceration, or, less frequently, to accompanying

peritonitis; not an offensive discharge, because this, too, marks the necrotic processes of the advanced stage of the disease, and is more often absent than present; not the so-called "cachexia," on which so much stress is laid, for that is simply due to the septic absorption which attends extensive ulceration of the malignant growth. Hemorrhage, and hemorrhage of an irregular type, is the symptom which should awaken sinister suspicions, and lead to a careful examination of the patient, especially if it occurs after the menopause. It is a mistake to think that patients with malignant disease have from the outset profuse flooding, as do those with fibroid uteri. The escape of blood is rather an occasional "show," appearing especially on exertion. After the climacteric the patient sometimes labors under the delusion that her menses have returned; before that time she may think that it is only some irregularity of menstruation. A slight loss of blood after coition, which is so significant in commencing epithelioma of the cervix, is not usually observed in cancer of the body.

Sooner or later other symptoms appear; first pain, then a gradual depreciation of the vital forces, later a fetid discharge, though the latter is often conspicuous by its absence. An attempt has been made to draw a sharp line between epithelioma and round-celled sarcoma of the endometrium, though the distinction can hardly be made clinically. With sarcoma the patient, who has usually not reached the menopause, has menorrhagia rather than atypical hemorrhages, less pain, an offensive odor is less often noted in the discharge, and the constitutional disturbance comes later—in fact, all the symptoms make their appearance slowly, and are less alarming at the first. If I were to characterize any symptom as pathognomonic, I would exclude pain, hemorrhage, and cachexia, and would choose rather the peculiar reddish, watery discharge, "like the washings of raw meat," as a German writer has described it. As regards general symptoms, patients with sarcoma present an extremely pale, anæmic (often dropsical) appearance, as contrasted with the so-called "cancerous cachexia."

The symptoms of adenoma are thus described by Winckel: " . . . the chief symptoms are abdominal and sacral pain, painful spasmodic contractions, nausea, profuse watery discharges, and irregular, frequent, and severe hemorrhages." So-called "uterine tenesmus" is not peculiar to malignant disease; too much stress is laid upon it by some writers.

The question of differential diagnosis is an extremely practical and important one. In my experience the two conditions which are constantly mistaken for malignant disease of the endometrium are hyperplastic endometritis (*endometritis fungosa*) and intra-uterine fibroid, especially if the latter is sloughing. The history frequently aids us but little. If the patient is in the prime of life, and has the symptoms which we usually associate with subinvolution due to some puerperal lesion, and the hemorrhage is a pure menorrhagia, with no intermenstrual flow or watery discharge, the probabilities are that the case is one of simple fungous endometritis. If it is, the dull-wire curette may be relied upon to settle the diagnosis, for however doubtful may be the result of the examinations of cancerous and sarcomatous scrapings (which are often so necrosed as to show no characteristic appearances), I have found that there is seldom any doubt about the microscopic appearances of "fungosities." During the five years in which I was pathologist to the Woman's Hospital I had ample opportunities for observation in this direction, and was able repeatedly to pronounce against the diagnosis of malignant disease by an examination of scrapings. As negative evidence this is invaluable. I say "negative," because in many cases in which we suspect the presence of sarcoma the microscope does not furnish such positive evidence as we could wish. This I showed in a former paper on "Sarcoma Uteri," *New York Medical Journal*, July 21, 1883), in which I stated that repeated examinations of scrapings from four probable cases led to conclusions similar to those of Gusserow, viz.: "The microscopical examination of isolated masses does not lead to a very definite conclusion; we often meet with bits of sarcomatous tissue which are made up of perfectly healthy mucous membrane, and, on the contrary, in cases of simple hypertrophy, with pieces which resemble small-celled sarcoma." Personally, I believe that round-celled infiltration, observed in sections of the hypertrophied endometrium, is most often mistaken for sarcoma.

I am glad to find that Heitzmann (in the article alluded to) is in accord with me on this point, because gynecologists are always complaining of the want of positiveness in pathologists' reports on scrapings. Remember that this hypertrophy of the endometrium is a common accompaniment of fibroid tumors, even when these are of small size, so that the presence of the latter growths, accompanied by the hemorrhages referred to, need not cause alarm. As is well known, the menopause may be delayed in consequence, hence arousing the suspicion that a malignant growth is developing. Moreover, pain and a profuse (but not fetid) discharge are not seldom present. Yet I have had several cases at the Cancer Hospital in which this suspicion was so strong that it was only allayed after two or three thorough scrapings, with careful examinations of the tissue removed, since the patients had the pains and decline of health which we associate with cancer. Twice during the past week I have operated upon patients near the time of the menopause, who had been carefully watched by their physicians for months, without their feeling positive that the condition was not more serious than appeared at the time of operation. It is always gratifying to be able to say that even the most alarming symptoms can be referred to intra-uterine growths of a benign character. A small submucous polypus will sometimes give rise to symptoms which closely simulate those of malignant disease. When we remember that these growths may become sarcomatous, it is evident that they are not entirely harmless. There is only one sure way in which to settle the diagnosis, and that is to dilate the cervical canal (preferably with tents) and to explore the uterine cavity with the finger, as well as with the curette. I consider my failure to do this in two of my cases of extirpation as reprehensible, though the diagnosis, based on symptoms and the examination of scrapings, was confirmed after removal of the uterus. We need all the evidence that we can obtain, and ought not to venture upon a serious operation as long as any reasonable doubt exists as to the nature of the disease.

Hemorrhage after the climacteric has been fully established is, of course, a very significant symptom, and when accompanied by pain, offensive discharge, and declining health is pathognomonic; but even under these circumstances it is our duty to ascertain the exact condition of the endometrium. I have, in common with other gynecologists, removed sloughing polypi, which have caused the patient and her physician grave anxiety, and have seen these symptoms disappear promptly.

I have not mentioned sloughing retained placenta as a condition which might be mistaken for malignant disease; but here ordinary attention to the history will give a hint of the true state of affairs, which will be confirmed by dilatation and the use of the dull-wire curette, with an examination of the material removed. You will see that I have laid stress upon the microscopical examination. It should never be omitted, any more than the search for casts in albuminous urine. Only by the application of all the aids of modern science, as well as of common-sense, can we avoid lamentable errors in diagnosis, and still more serious ones in treatment, such as have happened in the practice of the most eminent surgeons.

With regard to the treatment of malignant disease of the corporeal endometrium I think there should be little difference of opinion at the present day. Provided that the diagnosis has been made sufficiently early, while the uterus is still movable and the patient is in fair condition, there

is only one course to pursue—to extirpate the diseased organ without delay. I believe that the vigorous application of the sharp spoon or curette to the uterine endometrium under these circumstances, as recommended by some eminent gynecologists, is attended with great danger; in fact I made an autopsy in a fatal case of perforation by the sharp curette and removed a uterus per vaginam, the wall of which would certainly have been scraped through, even with the exercise of the greatest care. What do we accomplish by so-called palliative treatment? If the patient is in the early stage of the disease, we injure her chances of recovery from a subsequent radical operation; if ulceration is already advanced and the uterine wall is generally infiltrated and softened, we expose her to the imminent risk of death from perforative peritonitis. An occasional application of pure carbolic acid or iodine and antiseptic injections (especially of creolin) are all that most surgeons will venture to use after they have decided that extirpation of the uterus is unjustifiable.

It would be unjust not to refer in this connection to the excellent results obtained by Pawlik and Byrne with the galvano-cautery, even in cases of carcinoma of the corpus uteri. The latter states that in four out of eight cases of primary cancer in which he used the cautery the average period of relief from hemorrhage, pain, and foul discharges was two years. It is unnecessary to add that only one who has had the most extended experience with this instrument (and they are very few) should venture to introduce it within the uterine cavity under the conditions mentioned.

I have come to the conclusion, after a careful review of the statistics of vaginal hysterectomy and personal observations in twenty cases, that the only cases in which vaginal hysterectomy is justifiable are those of carcinoma, sarcoma, and recurrent adenoma of the corpus uteri in which the patient has been under observation sufficiently long to have the diagnosis established, and an examination of the uterus and its interior under ether has demonstrated both the nature of the disease, the mobility of the uterus, and the absence of serious complications, either visceral or in the glands and perimetric tissues. As Greig Smith aptly expresses it: "The patient must be in fair health, with a prospect of average longevity from general soundness of organs apart from the malignant disease."

This may be a narrow limitation of the operation, but I believe that it will one day be accepted by those who aim at remote, rather than at immediate, results in the treatment of malignant disease. The most serious criticism of American statistics (and this applies to those of laparotomy as well as of vaginal hysterectomy) is that they are so imperfect as regards the after-history of patients. We are so anxious to rush into print that we cannot wait until two, four, or even six years have elapsed before reporting the ultimate results of an operation. We consider our patients as "cured" when they leave the hospital without bad symptoms. How superficial such a course is in comparison with the practice of German surgeons! It is calculated to bring us into great disrepute abroad, and to render our statistics valueless from a scientific stand-point. "I cannot conceive any good object," says Williams, "in operating upon a patient on a Monday and reporting the case on a Thursday, and then burying it out of sight forever."

I am not able to make a positive statement with regard to the ultimate results of extirpation of the uterus for cancer of the corpus uteri, as compared with those following hysterectomy for cancer of the cervix, but in suitable cases they are decidedly better. Ont of Kaltenbach's recently reported cases of vaginal extirpation (sixty in number) seven were for malignant disease of the corpus uteri, and there was no recurrence in any of them—I mean under the conditions which I have already mentioned as alone justifying the radical operation. Though no actual data are available, gynecologists agree that the perimetric tissues are less likely to be involved in the former case, and therefore that when we have removed the uterus we have eliminated all the disease. On the other hand, the average duration of life in cases of untreated cancer of the body is thirty-one months (Pichot). Sarcoma may run a course of two or three years, and patients with adenoma may live still longer with palliative treatment. That there is always an element of doubt, even in the most favorable cases, was shown in two instances in which I performed autopsies upon patients who were in good condition at the time of the operation, which was uncomplicated; one patient with sarcoma of the corpus uteri had metastatic deposits in the intestines, the other with cancer of body of the uterus had both lungs studded with cancerous nodules, but in neither instance were there any evidences of secondary malignant disease within the pelvis. Consequently, when we speak of "curing" these patients we must not be over-confident. All that we can say is that in favorable cases of cancer of the body of the uterus we may hope to relieve the patient for a considerable period, to prolong her life for two or three years, or rarely for five or ten; that in cases of sarcoma of short duration the prospect of permanent relief after hysterectomy is still better, while in those of adenoma which has not yet assumed a well-marked malignant type (as in the two cases to which reference has been made) there is every reason to expect that the patient will be cured by extirpation of the uterus.

There are certain precautions to be observed in the removal of a uterus, the fundal wall of which has been softened by infiltration with malignant disease, as I have learned from personal experience. In the first place, it is highly desirable before beginning the operation to ascertain if the organ is not too large to be removed through the vaginal wound. I was on two occasions considerably embarrassed by the large size of the fundus, and I have known of the operator being obliged to open the abdomen in order to complete the operation, thereby adding immensely to its risks. Again, the position of the uterus should be noted, else one may lose valuable time in trying to antevert an organ which is retroflexed and adherent. I have found it easier to retrovert the uterus, rather than to antevert it, as is my practice in cancer of the cervix. A small, but important, detail is not to introduce the utero-tractor into the uterine cavity, since it almost invariably tears out and is apt to perforate the wall, allowing septic material to enter the peritoneal cavity at an early stage in the operation, as well as causing it to escape from the cervix and ooze over the vaginal wound. It is better to plug the cervical canal with iodoform gauze, and to make traction upon the cervix alone. Caution should also be exercised in drawing down the fundus, lest the softened uterine wall should be badly lacerated by the tearing out of the hook or volsella, allowing acrid pus to escape into the cavity, as has happened to me, once with bad results. In short, more than ordinary care must be exercised in handling the uterus not to perforate its wall. The ovaries and tubes should invariably be extirpated, even at the risk of considerably prolonging the operation, as it is a well-established fact that in malignant disease of the corpus uteri the mucous lining of the tubes is liable to be affected by direct continuity; hence there is a special reason for insisting upon their complete removal which is not present in cases of cancer of the cervix uteri.

But, even after using the greatest care in the selection of proper cases for operation, and limiting himself strictly to such as I have described as alone suitable for hysterectomy, the conscientious surgeon, however elated he may feel at the completion of an operation rapid in its execution and faultless in its details, must in his heart acknowledge the truth of Reeves Jackson's criticism that "the successful removal of a cancerous uterus is a very different thing from the successful removal of a uterine cancer."

Appended are the condensed histories of four typical cases of malignant disease of the corpus uteri, three of which occurred in my service at the New York Cancer Hospital:

Case I. *Epithelioma Corporis Uteri.* — The patient was fifty-one years of age, and had had little or no pain prior to her entrance into the Cancer Hospital, in October, 1888 (service of the late Dr. J. B. Hunter). She had never had any fetid discharge, nor any hemorrhage other than an occasional "show" of blood. Considerable doubt was felt as to the diagnosis because of the excellent condition of the patient. The dull-wire curette was introduced after she was under ether, and brought away a quantity of grayish, brain-like material, which was, at the time, regarded as typical sarcoma. Vaginal hysterectomy was performed, the broad ligaments being secured with clamps. The patient made a rapid recovery, and returned home at the end of four weeks.

[In discussing this case, when reported at a meeting of the New York Obstetrical Society, Dr. Byrne said: "I have seen quite a number of cases of intra-uterine cancer of the character shown in the specimen, and I have been repeatedly struck with the fact that in many of them there is not only no cachexia, but nothing to indicate that serious trouble exists, except hemorrhage. With regard to the pain said by nearly all authors to be almost characteristic of intra-uterine carcinoma, it is not borne out by clinical experience. . . . The pain so much spoken of by some authors, both old and recent, is purely fictitious."]

After Dr. Hunter's death the patient came under my care. She remained in good health for nearly a year, when she began to have pains in the back, with an occasional slight discharge of blood. On examination I found a suspicious, angry-looking nodule at the posterior edge of the wound. This has increased in size until it has become a mass as large as a small orange, which encroaches upon the rectum. It bleeds easily to the touch, but seldom spontaneously. There is no offensive discharge, the patient remains comfortable, and her general health has not yet been impaired.

Case II. *Epithelioma Corporis Uteri.*— Mrs. C——, aged fifty-five, a widow, had borne seven children, the youngest aged fourteen. Her grandmother and an aunt died of carcinoma uteri. She passed the menopause at forty-eight, and enjoyed perfect health until nine months before I saw her, when she first noticed an occasional slight bloody discharge from the vagina, which later became quite constant but odorless, and was accompanied by backache and occasional shooting pains through the pelvis. Her health was not impaired, and she presented the appearance of a robust woman. Two or three months before she was seen by me I examined some material curetted from the uterine cavity by the late Dr. Hunter, not knowing the history of the patient, and reported that it was probably round-celled sarcoma; I afterward learned that this was the patient in question. During Dr. Hunter's illness, April, 1889, she was sent to the Cancer Hospital by her physician, Dr. Pettit, and came under my care. I examined her several times, removing with the curette bits of soft, friable material, which under the microscope presented numerous groups of cells of an epithelial type, but no distinct alveolar structure. The uterus was large, retroflexed, and fairly movable; the endometrium was soft and spongy, bleeding easily. As the patient was apparently in perfect health, there was no foul discharge, and the microscopical evidence was not positive, I was not sure of the diagnosis and asked Dr. Bull to see the patient in consultation. He believed that the condition was malignant disease of the corpus uteri, and advised extirpation of the uterus. Another fragment of tissue was removed from the interior of the uterus, and was submitted to the pathologist. After a careful examination he was unable to find microscopical evidences of malignant disease.

The operation was somewhat complicated, and occupied nearly an hour. Not only was the uterus retroflexed and firmly adherent, but its wall was so softened that the utero-tractor, though introduced to the fundus, tore out several times. There was an enormous cystocele, which rendered it difficult to separate the bladder and to keep it up out of the way. In drawing down the fundus with a volsella, the wall was perforated, and a quantity of soft, brain-like material oozed through the opening into the peritoneal cavity; it was thoroughly sponged out. The adnexa were also removed with some difficulty. The broad ligaments were secured with compression-forceps, which were removed at the end of thirty-six hours. The patient made a good recovery, and after cicatrization was complete her cystocele was found to be almost cured. She is now enjoying good health.

The case was of interest from the stand-point of diagnosis. Here was a patient with slight, irregular hemorrhages (appearing after the menopause had been fully established), no foul discharge, little if any pain, and in appearance the picture of health. Several suspicious fragments were removed from the uterus by the curette, and were examined microscopically without positive results. A competent pathologist reported that the fragment sent to him was simply granulation tissue; he had received a portion that was undergoing ulceration. In spite of the negative evidence, the body of the uterus was found at the operation to be so extensively diseased that the wall would soon have been perforated.

[I quote from Dr. Wylie's remarks on this case, when it was reported at the Obstetrical Society, to illustrate what I said about loose statements regarding the frequency of certain rare pathological conditions:

"I think the percentage of cases of cancer of the body of the uterus given by Dr. Coe is entirely too small. According to my own experience I would place it nearer ten per cent. One reason why it has been placed much lower is the probable fact that many cases have not been diagnosticated. Out of six or seven cases in which I have done hysterectomy for cancer this year, two were cases of cancer of the body of the uterus. With regard to the microscopical examination, I may say that practically I consider it worth hardly anything. With regard to the use of the curette, I think that where the uterus is firm there is no more danger attending the steel instrument than the other. It has the advantage of leaving a smooth surface and not macerating the tissues. I have sent the material scraped away by the curette to as many as three pathologists for microscopical examination in some cases of cancer of the body of the uterus, yet all were unable to make a diagnosis. They could simply say that it was doubtful. Now, when a woman comes to me with a history of flowing two or three years, especially if it is five or six years after the menopause, and the flowing cannot be readily accounted for in any other way, I am prepared almost to take it for granted that she has cancer, if not of the cervix, then of the body of the uterus. In two cases within about a year, I curetted the uterus on three occasions; microscopical examinations were made with more or less negative results; then, taking the history as a guide, I performed hysterectomy, and in both cancer of the body of the uterus was found. Since we have learned to recognize these cases, we will have more of them than formerly. Some of the patients have only a little watery discharge, with admixture of some blood, continuing perhaps two, three, or even five years, until the body of the organ has become largely involved, while the internal os is nearly closed and the cervix apparently normal."]

Case III.—Mrs. McC——, aged sixty-three, entered my service in December, 1889. She was a widow who had borne seven children, and stated that her health had been good until seven months before, when it began to decline without any assignable cause. About this time she began to have occasional slight hemorrhages. For a few weeks prior to her entrance she suffered with severe backache. While under observation in the hospital she had no pain or hemorrhage, and there was only a slight, non-offensive vaginal discharge. In this case I settled the diagnosis positively by dilating the cervical canal with tents, and introducing my finger into the uterine cavity. A number of soft cauliflower masses were felt on the posterior wall, one as large as a marble, from which I re-

moved a good sized piece with the sharp curette. It showed under the microscope the structure of adeno-carcinoma. A week later I performed vaginal hysterectomy, using the clamps. The operation presented no especial difficulties. The ovaries and tubes were removed. The patient, being an alcoholic, had an attack of delirium tremens, jumped up and walked around the ward on the third night after the operation, but suffered no ill effects from it and was sitting up before four weeks had elapsed. She was discharged well, and will be kept under careful observation.

Case IV.—Miss F——, aged fifty, entered my service through the courtesy of Dr. Cleveland in December, 1889. She had reached the menopause seven years before; two years later she began to have slight hemorrhages at infrequent intervals, but had never had any offensive discharges. She was in the Newark Hospital in March, 1889, when the uterine cavity was thoroughly curetted, and this operation was repeated at the Woman's Hospital in September of the same year, but, unfortunately, no examination of the scrapings was made. The hemorrhages were always checked after each curetting, but in a few weeks they recurred.

For a few months prior to her entrance she had had severe paroxysmal pains, which began about eleven o'clock every morning and lasted from two to four hours. On entrance the patient's general health was excellent. I found her uterus small, movable, and insensitive. The introduction of a dull-wire curette gave pain and caused a flow of blood. I removed a small bit of tissue, sections of which I examined microscopically without positive results. I could say positively that it was not fungous endometritis, and that it was not sarcoma. In one section the presence of groups of epithelioid cells pointed to a cancerous element. Taking all the evidence into consideration I came to the conclusion that there probably existed malignant disease of the corpus uteri, and decided to perform hysterectomy. The operation was the most difficult that I had ever seen or done, as the patient was a virgin and the working space was so limited that it was necessary to divide the perineal body and to incise the vaginal wall in order to gain room. It was impossible to reach and remove the ovaries and tubes, or to apply a single ligature. The patient had considerable shock, but rallied well, and is now in good health and entirely free from pain.

Dr. Freeborn, the pathologist, reported that the specimen was a rare and interesting one, since microscopically it was a papillary adenoma. It was strictly limited to a small area on the posterior wall. He regarded it as clinically only a little less malignant than cancer, an opinion fully confirmed by its rapid recurrence after curetting. He had seen only one other specimen—Dr. Bache Emmet's, to which allusion has been made. The prognosis as regards a permanent cure is better than in any case that I have seen.

[Since writing the above I have extirpated a uterus which was the seat of round-celled sarcoma of the corporeal endometrium. The patient was referred to me by Dr. A. M. Jacobus, who had made a diagnosis of probable malignant disease several months before. The operation was quite easy, but the patient was in poor general condition, having contracted kidneys, and died on the fourth day.]

Tight Collars and Vision.—The influence of tight collars in impeding the circulation in the head by pressing on the jugular veins is well known to military surgeons with the troops in India; but the bad effects of such pressure in cooler climates has been demonstrated by the observations of Professor Förster, of Breslau, who states that three hundred cases have come under his notice in which the eyesight has been affected by the disturbance of the circulation caused by wearing collars that were too small. A large number of these cases were probably subjects of myopia.—*The Lancet.*

THE SUCCESSFUL REMOVAL OF AN ANTERIOR ENCEPHALOCELE.

By W. F. MITTENDORF, M.D.,

NEW YORK.

Among the tumors of the head connected with the cranial cavity encephaloceles appear to be the most frequent, and yet they are fortunately quite rare, especially the anterior and lateral ones.

These tumors are, with very few exceptions, congenital malformations and vary considerably in regard to size, location and contents. At the time of birth they are usually small, but their tendency is to grow rapidly, and some of them attain a size almost equal to that of the head. They are usually found posteriorly, but quite a number of them have been found in the median line of the face over the root of the nose. Very few cases have been observed where the protrusion was in the temporal region and those projecting into the mouth, between soft and hard palate, are very rare. Out of ninety-three collected cases (Hurd) only sixteen were over the nose.

Fig. 1.

The mode of development of these tumors can perhaps not be fully explained. Some authorities suppose that an intra-uterine hydrocephaloid condition must be present in order to cause a prolapse of meninges or of the brain itself. It is, however, more than likely that a small prolapse or folding of the dura-mater before union of the bones takes place has more to do with it than an imperfect bony union inviting a prolapse.

The three varieties of these tumors, arranged according to the frequency they are met with, are those containing cerebral matter surrounded by the meninges, known as encephalocele or hernia cerebri. The second form is where this condition is accompanied by hydrocephaloid changes; it is spoken of as an hydrencephalocele. The third form, the rarest of all of them, is a prolapse of the meninges alone, the prolapse being greatly distended with fluid. This is known as a meningocele.

The prognosis of all of these deformities is very grave; the sac becomes more and more distended until it bursts, or sloughing of it will lead to a rupture and cause the death of the patient. The prognosis of an encephalocele is perhaps a little more favorable. In such a tumor, if it has a small pedicle, sacculation and separation from the cranial cavity may take place, in which case the growth of the prolapse is arrested, and even if rupture should occur it is not necessarily fatal. If death does not occur, there is, however, great danger that the patient will become more or less idiotic or paralytic.

A case of this kind presented itself to me at the New

York Eye and Ear Infirmary a little more than two years ago. The patient a well-developed male child, four days old, had the appearance which is faithfully represented in Fig. 1.

The history, as told by the midwife in charge of the child, is as follows: At the time of birth the child was found to have a swelling of the thickness of an ordinary lead pencil, extending along the left side of the nose and covering the left eye to a great extent. As soon as the baby was being washed and commenced to cry the tumor began to enlarge and had grown so rapidly that on the fourth day, when I saw the child, it had the size of a pigeon's egg and as soon as touched, or rather as soon as the child began to cry, it would become tense and swell considerably. The tumor was not covered by integuments, it appeared like a membranous bag, here and there covered by crusts, and having some blood-vessels running over it. It was semi-transparent, but although most of its contents were of a liquid nature the absence of blood could be easily diagnosed on account of its transparency when tested by the light of a candle, and on account of its pale, almost transparent appearance. The presence of brain-matter however, remained doubtful, as moderate pressure, carefully applied, failed to empty the contents to any great degree. The tumor covered the left eye completely and appeared firmly attached to it, and as there was a large cleft of the left wing of the nose, apparently extending up to the pedicle of the tumor, the first thought was that I had a degeneration of the tear-sac to deal with.

However, after placing the child under chloroform, which became necessary, as it was very restless and cried constantly, it was found, after soaking and removing the crusts gluing the tumor to the cheek and eyelids that there was no connection whatever of the growth to the eye, nose, or tear-sac. It proved to have started from the median line of the forehead, between the eyebrows and apparently from the lower portion of the frontal bone. It had a rather thick pedicle, which was surrounded by the integument of the face; this did not extend far over the tumor, which externally was composed of a transparent membrane with a number of very little blood-vessels running over it. The size of the tumor had somewhat diminished as soon as the child had become quiet, and gentle pressure resulted in evacuating some of its fluid contents so that it became quite flaccid, but like a mass of erectile tissue it filled anew, and the growth became hard as soon as the child began to recover from the effects of the anæsthetic and began to cry. The diagnosis was now easy, the existence of a fissure of the skull could not be felt through the skin, but that the protrusion was connected with the brain, or at least with the arachnoid spaces, could no longer be doubted.

The eye as well as the tear-sac were perfectly normal, and the cleft of the left nostril extended not quite to the inner corner of the eye. It was evidently caused by pressure of the thin smaller growth during intra-uterine life. The hard as well as the soft palate were perfectly normal and the child, an unusually large one, was perfectly developed in every other respect.

A photograph of the child was now taken and the parents were informed of the nature of the tumor and the possible consequences of an operation. Both parents agreed cheerfully to the operation, however—in fact expressed themselves emphatically that they would rather take the risk of having the child die in consequence than to have it deformed for life. The tumor showed an alarming tendency to grow, and on the sixth day after birth—that is, two days after its first visit to me—the growth had become, if distended, as large as an ordinary hen's egg.

Dr. Robert Weir and Dr. Richard H. Derby, who had seen the case in consultation, advised likewise an immediate operation, on account of the rapid growth of the protrusion.

The operation took place on December 12th, the child being six days old. Chloroform was used to produce narcosis. The integument was then incised a short distance from and around the pedicle. After the base of the pedicle had been thoroughly exposed a strong catgut ligature was passed around it, as near to the bone as possible, and firmly tied. After this the tumor was removed by cutting it off with a scalpel. I left, however, nearly a quarter of an inch of the pedicle to prevent the ligature from slipping off too readily.

The surrounding integument was now incised and dissected up sufficiently so that it could be drawn over the stump. It covered the pedicle completely, leaving only a small drain at the lower portion, and the ends of the catgut suture served as a drainage-tube. The integument of the upper portion was connected with that of the nose by several stitches. This was done partly to leave as little deformity as possible and partly to protect the stump from external injurious influences, and partly to prevent the catgut ligature from slipping off, if the pedicle should begin to shrink.

Fig. 2.

After some difficulty to revive the child, which had stopped breathing near the end of the operation, a dressing of absorbent cotton, soaked in a 1 to 2,000 solution of bichloride of mercury was placed over the wound and held there by a pressure bandage. The child was then sent back to its mother.

The dressing was renewed daily. The upper portion of the integument healed rapidly, and made an excellent covering of the stump. In the lower part of the wound, near the nose, the stitches tore through and this portion healed slowly by granulation.

About the eighth day after the operation most of the catgut came away and healthy granulation filled the lower part of the wound. The upper part of it was now quite firmly united, and in a short time the wound had entirely closed, leaving but very little deformity; nor had the child shown any unpleasant symptoms whatever during this time, nor later.

This picture represents the child nearly three months after the operation. When it was about six months old the coloboma of the nose was operated upon, and up to that time the boy had grown well and appeared to be as intelligent and strong as any child of its age.

The child is the third one of its mother, and none of its brothers, nor its father or mother, show any deformity whatever.

In regard to the tumor, I have to state that at the time of the operation most of its fluid contents, consisting of

a clear, straw-colored fluid, here and there mixed with a little blood, escaped, that the pedicle was about as large as my little finger, and that very little bleeding took place at the time of the operation.

The growth was located at the root of the nose, and had apparently left the skull between the cribriform plate of the ethmoid and the frontal bone, and appeared anteriorly between the frontal and nasal bone.

On removal the tumor itself was found to measure $30 \times 24 \times 16$ mm. It had about the size and shape of a somewhat flattened rubber nipple, and at its constricted pedicle, the cut surface measured 11×7 mm.

After hardening in Mueller's fluid, and subsequently in alcohol, longitudinal and transverse sections were made by my friend, Dr. Lennox, and examined with the following results: The tumor consists essentially of three parts—an outer connective-tissue envelope, partially covered by epithelium, an inner solid mass made up of tissue resembling cerebral cortex, and an intermediate space, cut up by irregular bands of fibrous connective-tissue into smaller spaces more or less completely filled with coagulated fibrin and small round cells. The epithelium covering the outer part of the tumor is laminated, the inner cells being columnar, the middle polygonal, and the outer flattened. The epithelium is not present over the entire surface, there being extensive superficial ulceration, and in places it is apparently infiltrated with fluid, the outer cells being separated from the inner by irregular spaces, and by irregular, larger, or smaller cavities or vacuoles, formed sometimes in, sometimes between the cells. The epithelium rests on a fibrous basement substance or membrane, which is smooth and shows no tendency to the formation of papillæ. It is largely infiltrated with inflammatory products, and, as already said, is extensively ulcerated in places, the surface of the ulcer being covered with a granular detritus. The central mass of the tumor has, as I have said, the appearance of the cortex of the cerebrum. It consists of a somewhat granular matrix containing numerous larger and smaller round and branching cells, together with numerous blood-vessels. The latter, chiefly capillaries, are distended with blood, and have ruptured in places, thus giving rise to irregular hemorrhages, which may be found scattered through the specimen. This central more solid portion is somewhat more than half as large as the whole tumor (it measures 16×7 mm.), contains a narrow, slit-like space filled with blood and coagulated fluid, and is enclosed by a highly vascular connective-tissue envelope. Between this envelope and the outer fibrous covering of the tumor is the irregular reticulated space which, before removal of the tumor, was filled with fluid and now contains coagulated fibrin and pus-cells. Indeed, the whole specimen shows marked evidence of inflammation, together with extreme vascularity.

The examination shows the case to be one of encephalocele, the prolapsed cortex being enclosed in the somewhat modified brain membranes, and the whole showing the changes incident to the accompanying inflammatory action.

In conclusion I would state that the result of this case speaks strongly for an operative interference in cases of meningocele, and likewise in those cases of encephalocele where a comparatively small pedicle exists; that the operations should in these cases be performed as early as possible, and that there is very little danger of meningitis if the necessary antiseptic precautions are observed.

The child at the present time is doing well in every respect. There is hardly any scar left and the mental faculties do not appear to be disturbed in the least. The mother seems to think that the child is unusually bright and lively.

A Fully Equipped Bathing establishment with all that is to be found at the best Spas of Europe will, it is said, be erected at Richfield Springs. We are also told that a Zander Institute with all the Zander machines is to be established in this city.

A CASE OF PLASTIC BRONCHITIS IN A CHILD.

By CHARLES LEWIS ALLEN, M.D.,

NEW YORK.

Fibrinous or plastic bronchitis, occurring idiopathically, and especially in its acute form, and in children, is described in our text-books as a rare disease. *The London Medical Recorder* (quoted in the Medical Record of January 18, 1890) mentions that Dr. Samuel West has collected all the cases reported since 1869, and has found them to amount to fifty-two, the majority being of the recurrent type. Dr. West himself had seen but one case, this in a woman aged forty, the attacks recurring at intervals during two years. In consideration of these facts I am induced to report the following case:

Annie C——, a previously fairly healthy child aged seven, was taken sick on November 18, 1889. She complained of pain in the left side of her chest and of nausea. By the afternoon of the 19th she had grown worse, vomited occasionally, and had developed considerable fever and restlessness, and some cough. I saw her first at 1 P.M. on November 20th. Her face was flushed, and she appeared to have considerable dyspnœa; axillary temperature, 103.3° F.; pulse, 150; respiration, 60. On physical examination there was found some dulness and a few fine râles below the left clavicle; breathing slightly bron-

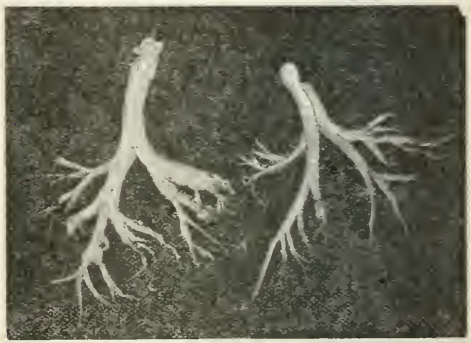

Fig. 1. Fig. 2.

chial; then, a little lower, a slightly tympanitic percussion note. I diagnosed beginning pneumonia; ordered a flaxseed poultice, and a mild expectorant cough-mixture, also two grains of antifebrin, given at once, and repeated that night if necessary. On the morning of November 21st she was seized with a fit of dyspnœa, and coughed up cast No. 1 of our plate, experiencing at once prompt relief. At 1 P.M. she seemed better; temperature, 102° F.; pulse, 144; respirations, 50. The physical signs remained about the same. No membrane could be detected upon the fauces.

On November 22d Dr. G. E. Billington saw her with me. We found her considerably better—temperature, 97° F.; respiration, 36. The dulness at the left apex persisted; there was marked diminution of the respiratory murmur in the same region; no râles to be heard, no membrane on the fauces, and no albumin in the urine. On the morning of the 23d, with the same train of symptoms, she coughed up cast No. 2. Both of these casts were expectorated at about 6 A.M. Temperature at 1 P.M., 98° F.; pulse, 104; respiration, 40. The dulness at the left apex was unchanged. A slight dulness was detected over the base of the right lung, and a few coarse and a few fine mucous râles diffused over both lungs. The child looked well and bright. After this I saw her every day until November 30th. The abnormal physical signs grew gradually less. On December 4th she was quite well, and only a suspicion of dulness over the left apex remained. I have seen her at intervals until to-day, March 5, 1890.

Her chest is now quite normal, and she has had no return

of the trouble. At no time had she any laryngeal symptoms. She is in good health, though slight, and rather sensitive to cold. The treatment was only that of ordinary catarrhal bronchitis. I wanted to give her alkaline inhalations, but found this impracticable in a tenement-house, and, in fact, at no time were her symptoms very urgent. The subjoined figure is from a photograph by Mr. Keenan, of the New York Polyclinic. Cast No. 1 is 3 inches long by $\frac{3}{16}$ inch at its greatest diameter; No. 2 is $2\frac{1}{2}$ inches by $\frac{1}{4}$ inch.

They were coughed up with some fatty mucus, and were pinkish white in color. They are partly hollow, a probe entering a short distance only. On microscopic examination a piece of No. 2 was found to consist of fibrin, with a large number of leucocytes.

136 East Forty-ninth Street.

SOME FACTS IN THE HISTORY OF DIPLOMA MANUFACTURE IN THE UNITED STATES.

By AUSTIN A. MARTIN, ESQ.,

BOSTON, MASS.

The recent action of the authorities of the University of Berlin in refusing to recognize American diplomas in their university calendar, again brings forcibly to mind the infinite harm done to the good name of American physicians by the wholesale manufacture of diplomas in this country. The appeal of the medical schools of Maryland to those of the rest of the United States, to unite upon some plan of action for improving and regulating medical education, will, it is hoped, result in some uniform and useful action in this direction, and tend to raise the standard in all honest and *bona fide* medical schools. Much as the general standard of medical education might doubtless be improved here, it is probably not this, but the wholesale and outrageous manufacture and sale of fraudulent diplomas in the past, that has influenced the German authorities in their action. It is the purpose of this article to review briefly some of the leading facts in this unsavory record of rascality.

A diploma is essentially a good thing to have. The veriest quack would naturally prefer one from one of the best medical schools of the country, to hang conspicuously in his office. He would much rather not enrol himself in the ranks of "natural healers." He wishes to be respectable, and by dint of "doctoral conduct" and persuasive arts to take good rank in the profession. He knows the power of wheedling manners, unblushing effrontery, and shrewd longheadedness. He knows it is of no use to go to any of the leading medical schools. That would involve at least three years' study and attendance. He has no time or inclination for such old-fashioned methods. He does not dare to insert his name in the diploma of a deceased physician. That is too risky. How to meet the difficulty? The genius of John Buchanan, of Philadelphia, the great inventor of diploma manufacture pure and simple, rose to the occasion and supplied the long-felt want. The first requisite was that the diploma should be conferred by a regularly chartered medical college; second, that it should be attainable in the shortest possible time; and third, that it should be handsomely engraved, and sealed in due form, and, preferably, in Latin.

His reputation was not such as to make it probable that, even in the slipshod manner in which legislation is often conducted, he could form new colleges by special charter. In the emergency it occurred to him to get control of, and revive some regularly-chartered colleges which had practically perished of inanition, but whose charters had never been annulled. This was not difficult to manage. Armed with the college seal, and blank diplomas, taken from some dusty drawer or closet, and bought for a small sum, he was in position to start in trade. Subsequently he did succeed in getting charters for one or two new colleges, which were conducted in the same way as the old ones. Indeed, emboldened by this success, he also sold diplomas purporting to come from institutions which had not even the pretence of a legal existence. It was rather, however, on those which had an actual legal existence that he relied. Then commenced a most wholesale and disgraceful manufacture and sale of diplomas. The difficulty was, that this rascal controlled colleges whose charters were still in full force, with "a faculty," like "men in buckram," it is true, but yet capable of signing their names legibly to a diploma. The whole farce was kept up, even to holding meetings of the "faculty" and keeping records of their proceedings, and issuing lecture tickets and certificates of matriculation. Indeed, until he became bolder, and took other steps which brought him within reach of the law, his graduates were legally doctors of medicine. He had the audacity to test the question in the courts, which were obliged, under the facts in the case, to sustain the legality of his charters. Emboldened by this, he became more and more reckless, openly advertised his diplomas, and had agents for their sale both here and abroad. Immense numbers were sold in Europe, especially in Germany, where the American Minister at Berlin openly denounced them as fraudulent.

He was finally caught by a newspaper man, John Norris, of the Philadelphia *Record*, to whom under various fictitious names, he sold no less than eight diplomas, conferring several degrees of M.D., one of D.D., one of D.C.L., and one of LL.D. Some of these were technically legal in form, but some absolutely fraudulent. Upon his arrest the whole paraphernalia of his fraudulent operations were captured, and ample evidence to convict him was secured in his correspondence and papers. A full *exposé* was published in the Philadelphia *Record* of June 10 and 11, 1880. His subsequent confession, giving full particulars of his operations, and implicating other individuals and institutions, appeared in the same paper, March 25, 1881.

To Buchanan belongs the discredit of first systematizing and cheapening the manufacture of diplomas. Doubtless the thing had gone on in a sneaking amateur manner before his time. It is not difficult to conceive that, in some of the inferior colleges, where the requirements were not very strict at the best, a pushing fellow who had decided to become a doctor, and to whom a delay of a year was a serious drawback, might make it an object for some needy or friendly instructor to pass him speedily in his particular course. The example might prove contagious; another might be found equally indulgent; until finally the payment for a year's tickets, and an actual stay of six or eight weeks would suffice to turn out a full-fledged M.D., against whom nothing could be said legally. True he might be utterly incompetent, with no knowledge of his profession beyond a few scientific words and phrases hastily culled from the fields of learning; but there he was—a doctor of medicine in name and legally.

These puny efforts were nothing compared to the Napoleonic proceedings of Buchanan. He it was who degraded American diplomas to such an extent in Europe that their name became a term of reproach, and good and bad were confounded together. The authorities at Berlin, in explaining their recent action, are reported to have said, that while they admit the existence of many excellent schools in America, they cannot attempt to discriminate between these and the fraudulent and worthless institutions which have disgraced, and still disgrace America. They urge the laxity of American laws in the matter of conferring degrees, as the reason for this step.

Buchanan's capture and imprisonment excited much public attention at the time, but the details of such matters are soon forgotten. The charters of his colleges were annulled; but many of the persons upon whom he had conferred degrees were legally doctors of medicine. There might be a cloud on their title in the eyes of honest men who knew the facts, but the parchment conferring the degree of M.D. remained.

The criticisms of the German authorities upon the lax

state of the law and the lack of uniformity as to any proper standard of medical education in America are unfortunately too just. The opportunities for quacks have been and are far too available. No better example of this can be found than the laws of Massachusetts between 1874 and 1883. Up to 1874 a special charter from the legislature was necessary in order to form a medical school. In 1874 an act was passed (Acts 1874, ch. 375) which, whatever may have been the intention of its framers, materially enlarged the scope of the existing law. This chapter provided in substance, that seven or more persons could form a corporation under the general laws, for "any educational, charitable, and religious purposes, for the prosecution of any antiquarian, literary, scientific, medical, artistic, monumental, or musical purposes," etc. It allowed such corporation to assume any name not previously in use by any existing Massachusetts corporation, and to prescribe by its by-laws the officers and agents by whom the purposes of its incorporation might be carried out. No capital was required, no restrictions as to the character of the instructors or the course of study—practically nothing to restrict its action. There was no provision expressly authorizing such corporation to confer diplomas, but there was nothing to prevent its doing so. No clause making it a crime or misdemeanor. What an opportunity! Slovenly and loose as legislation is apt to be, many a bold quack would hesitate before joining clairvoyants and other loose fish with himself, and applying in regular form to the legislature for a special charter for a medical school. Some pretence of stability and honesty of purpose would probably be required. But how different the ordeal under this indulgent statute! Six associates, five dollars for the certificate of incorporation, and, presto! the thing was done! Next a name, preferably a colorable imitation of that of some long-established school in another State, and then a well-executed plate in the Latin language, purporting to confer the degree of M.D., which work of art could then be sold to such as chose to buy. Several medical schools were actually formed under this statute, and given a name and existence by the authority and certificate of the State. The history of all of them is not known. One, which showed an honesty of purpose, was subsequently authorized by special law to confer the degree of M.D. One, the "Bellevue," so called, was detected in selling its diploma, without any pretence of a course of study, to a person under a fictitious name, who in his assumed character showed himself to be absolutely illiterate. The case was brought before the United States Commissioner at Boston upon a charge of using the mails for the purpose of defrauding, the diploma having been sent through the mail. The accused were discharged, the Commissioner ruling that nothing in the laws of Massachusetts prevented the school issuing its diploma to whomsoever it pleased. How many more such cases occurred is not known, but it is not uncharitable to suppose that there were many others. The legislature soon afterward passed an act (Acts 1883, ch. 268) forbidding these colleges formed under general laws conferring degrees, under a heavy penalty. None of the certificates of incorporation granted to them, up to the date of this later act, have, however, been revoked. Even the dishonest "Bellevue," so far as is known to the writer, still has a legal existence.

The instance of Massachusetts is cited merely as a well-marked example of the dangers of such loose and careless legislation.

Similar deficiencies exist in other States. All such facilitate the creation of utterly irresponsible schools, under a show of legal right. It is perfectly easy to stop this, by insisting upon a special charter for the formation of a college.

On the other hand, maintaining a high standard of medical education is by no means an easy problem for the legislature. It should, if possible, be attained in the first place by the combined and honest efforts of the best schools, fixing some standard of time and character of study below which no medical diploma should be granted. This standard should then be enforced by legislative enactment. Finally, no one should be allowed to announce himself as a doctor of medicine without such recognized diploma, or until after a suitable examination by a thoroughly competent board. It may be difficult to prevent persons actually practising medicine or surgery without a degree. Patients stubbornly insist on their right to have anyone they please attend them. Let it be so. The status of such practitioners would be defined. The State, however, can and should see to it that no diploma be granted by any college except upon a thorough examination in a curriculum of a high standard. I am aware that legislation looking to the regulation of the practice of medicine is difficult to accomplish, owing to an unreasoning popular prejudice. The laws of the various States differ widely. In some there is no restraint whatever; anyone may call himself a doctor of medicine, may practice and collect fees without diploma or license. Others have a more or less effective system of licensing after examination. Illinois, through the State board of health, has done excellent work in the matter of careful examinations, and in exposing fraudulent institutions. Difficult though it may be, something like a uniform and effective system of examination and licensing should be brought about. The law should draw the line sharply between the honest and well-educated man, and the quack or incompetent, who, either with knavish purpose, or with culpable ignorance, would pose before the public with the insignia of a learned profession.

ON THE DEGREE AND DEMONSTRATION OF ASTIGMATISM AS DETERMINED, WITHOUT THE USE OF MYDRIATICS, BY JAVAL'S OPHTHALMOMETER, MODEL OF 1889.

By H. DRAPER SPEAKMAN, M.D., PH.D.,

ASSISTANT SURGEON MANHATTAN EYE AND EAR HOSPITAL, NEW YORK.

For several years hypermetropia and myopia were recognized and treated apart from astigmatism. So clearly was this separation made, that multitudes of patients were fitted with convex or concave glasses, and their astigmatism entirely overlooked. Later on came the discovery of normal astigmatism in his own case by the immortal Young, as published in "Philosophical Transactions," in the year 1793. Next came a case of abnormal astigmatism, reported in the "Transactions of the Cambridge Philosophical Society," in 1827, by the Royal Astronomer Airy, and he also reported his own case. Following these reports have been others too numerous to mention, in which every phase of the subject has been fully discussed. I will therefore hasten on to the subject proper of this paper as expressed by its title. And let me here state that I intend to confine my remarks entirely to regular abnormal astigmatism. Now for the point that we are all, as oculists, interested in mastering practically, viz., the degree or amount of astigmatism present in a given case. According to Donders, page 481, the "degree of astigmatism is found from the difference of refraction of the two principal meridians." It is at this point that I would take exception to Donders, and to all who have written on, or taught, the subject according to this definition, from his time to the present day. Practically, the degree or amount of astigmatism is found, not in the difference of refraction of the two principal meridians, for refraction includes the whole optical condition of the eye, as measured from the fundus to the external limit of the cornea, and must necessarily take into account all the existing hypermetropia or myopia in determining the degree of astigmatism present. But the amount of astigmatism is found by the difference between the two principal meridians of the cornea, as expressed in diopters and as measured externally. You will say at once, "This is all very well for determining the

amount of corneal astigmatism, but how about the other causes of astigmatism independent of the cornea?" Allow me briefly to enumerate some of these other causes. We have lenticular astigmatism due to one of the following defects: 1. Malposition, as in obliquity of the lens or from luxation. 2. Asymmetry of the lens, due either to unequal radii of curvature or to uneven action of the ciliary muscle. 3. Malformation of the lens; it may be nearly globular in form. 4. Pathological changes in the lens-substance, which in one way or another alter its index of refraction. And, lastly, there may possibly be an astigmatism due to unequal curvatures of the fundus in the region of the macula lutea. But this last must be extremely rare, as myopes are apt to be less astigmatic than hypermetropes, although, as we know, myopia is caused by changes in the fundus. While I admit that my definition does not include any of these forms of astigmatism, I still hold that for all practical purposes it is correct; and though granting that there is necessarily a variation in those cases where one or more of the above conditions are present, this variation is a constant one which can be provided for in our calculations. While in all methods our final test is made subjectively, how much easier it is to know within one-quarter of a diopter the existing degree of astigmatism objectively, and then rapidly check off this result by means of our subjective examination. If this will hold good in cases of normally acute vision, of how much more value must it be where a subjective examination is negative in its results, as is so often the case in children, and always in cases of conical cornea and in amblyopes? Donders admits that, of the different factors producing an astigmatism, the corneal predominates, and it is now an established fact that in the vast majority of cases this preponderance is very great. Allow me to quote from Swan Burnett, page 128, as follows: "Since, however, it is a fact demonstrated more than twenty years ago in the physiological laboratory, and now fully corroborated by this very instrument, an earlier model, in the consultation-room, that the much larger part of astigmatism is corneal, and since it is as easy with it to measure the cornea in one meridian as in another, the value of this keratometer in the diagnosis of astigmatism can hardly be over-estimated."

My second point is the demonstration of astigmatism. We now, with the various keratoscopes, can measure accurately the axes and the difference in the corneal curvatures, and express this difference in diopters of refraction. So accurate are the results with Javal's ophthalmometer, by which we can measure to within one-fourth of a diopter of corneal astigmatism, that the instrument may well be called a keratometer; and by still further applying the rule to be laid down in this paper, it virtually is an astigmometer, instead of an ophthalmometer.

We can now get the total corneal astigmatism in a case, and practically estimate the amount of astigmatism present, without knowing the further refractive condition of the eye, viz., whether hypermetropia or myopia also exist. So that we should do away with all the compound words used to express or designate astigmatism, viz., simple or compound, hypermetropic or myopic, and mixed astigmatism, and simply speak of astigmatism. These designations were necessary formerly, for it was only possible to measure from within out, whereas now we approach externally and determine both the axis and amount of the existing astigmatism. After the astigmatism is fitted, it is a simple matter to fit the hypermetropia or myopia with an ophthalmoscope, or by turning on spherical lenses behind one connecting cylinder. I should further state that Javal's instrument not only gives us the total amount of astigmatism present, but also designates the proper axis at which to place the concave cylinder used in correction. From the simplicity of hypermetropia and myopia we advanced into astigmatism, but we carried these two conditions with us and mixed them up as compounds of astigmatism, as, for example, hypermetropic or myopic astigmatism. Now, we can and should, I think, after in turn separating astigmatism from them by means of astigmometers; we should, I repeat, return to simplicity again, and only recognize and teach three conditions of refraction, viz., hypermetropia, myopia, and astigmatism. We will now pass on to the consideration of two groupings of astigmatism, viz., astigmatism with the rule and astigmatism against the rule. These terms are being used, and will in future, I think, be adopted universally. Experience has taught us all that a large proportion of cases of regular abnormal astigmatism are corrected by placing a plus cylinder at axis 90°, or a concave cylinder axis 180°; in other words, the vertical corneal meridian is usually more curved than the horizontal. This condition constitutes an astigmatism with the rule. But there are numerous exceptions, and in a number of cases the exact reverse is found, and the horizontal meridian is more curved than the vertical. This constitutes an astigmatism against the rule. Cases are grouped under one of these two classes as the axis of greater curvature approaches one or the other of these two principal meridians. An astigmatism axis 45°, is just half-way between these two groups, and we cannot as yet formulate any rule that will modify the amount of astigmatism found with Javal's instrument. It may be interesting to note the fact that in an astigmatism with the rule the vertical curvature corresponds to the proper curvature of an emmetropic eye, and that it is the horizontal meridian that is wrong. (See Donders, page 495.) While some recent observers have stated that astigmatism with the rule may be due to lid-pressure in the vertical meridian, I have not been able to find any reason given for the numerous exceptions which constitute the second group, that of astigmatism against the rule. I venture therefore to formulate a rule as follows: The axis of a corneal astigmatism is determined by the relative length of the palpebral fissure as compared with the horizontal diameter of the eyeball. Let me illustrate. If, on inspection, the palpebral opening presents an oval appearance, we should look for an astigmatism with the rule. If, on the contrary, the palpebral opening looks round, we should expect an astigmatism against the rule. After ascertaining from Javal's instrument (preferably his model of 1889, which is greatly superior to the preceding ones) the axis and strength of a concave cylinder required to neutralize the astigmatism present, it is a simple matter to correct the additional refractive error, be it hypermetropia or myopia, by adding convex sphericals, beginning with one rather stronger than our correcting cylinder. We all know how much easier it is to fit all refractive cases by using concave cylinders combined with plus sphericals. We obtain results so much more quickly that it is much more convenient for routine practice than the old method. The rule for using Javal's ophthalmometer is as follows: In astigmatism with the rule, the patient usually accepts three-fourths of a diopter less than the amount indicated by the instrument, while in an astigmatism against the rule, the patient may require three-fourths of a diopter more than the amount found. If there is no corneal astigmatism we should look for one-half diopter against the rule. By following the above rules, with slight modifications, Javal's ophthalmometer becomes in reality an astigmometer. We have then in this astigmometer an instrument by means of which we can fit an astigmatism without the use of atropine or any of the other mydriatics, and need only employ them in those cases where we wish to obtain their therapeutic action, as in spasm of accommodation and in the various diseases of the eye.

154 Madison Avenue.

An Alleged Cure for Hydrophobia.—Dr. Arapad Bokai, Professor at the University of Klausenburg, claims to have compounded a solution which completely neutralizes the poison introduced into the system by the bite of a mad dog. This solution consists of chlorine water, salt brine, sulphurous acid, permanganate of potassium, and eucalyptus oil.

JUSTICE TO HOSPITAL GRADUATES.[1]

A Proposal to Adopt the Title of H.G.S., Hospital Graduate, Surgical; H.G.M., Hospital Graduate, Medical.

By GEORGE E. ABBOTT, M.D.,

NEW YORK.

In looking over the student world I find that men have, from time immemorial, given many of their fellows certain titles, indicative of, and as a reward for, certain lines of labor which they have pursued.

These titles denote part of the work done by the individual, and are of much use to us, as are all diplomas and certificates. Thus we have Rev. and D.D.; Att'y, and LL.D.; Dr. and Prof.

Our colleges give the degree of Bachelor of Arts to their graduates, and, if subsequent years of study are successfully pursued, Master of Arts is the reward.

Thus we see that there are certain titles which represent to us the preparatory and advanced work respectively, which the possessor of the title must have accomplished, and if we are in search of a man of special attainments the title serves to indicate to us such an one as we seek; and we can go to him with the assurance of finding a man whose training has fitted him for the work we desire to have done.

In the medical world a large number of men after completing the undergraduate work, which secures to them the title of M.D., continue their studies, spending much time and constant labor to acquire a hospital training. Such a training is of far greater value to the sick and wounded than the undergraduate course which gave them their M.D., and gives an experience equal to many years of private practice. Yet, strangely enough, *of this hard work and valuable training no mention is ever made, no title given;* and these men of experience and ability go out here and there, just where their fellows need their aid and assistance; but our only means of finding them is by the accidents of personal acquaintance.

For example: A patient desires to go to a strange town, and asks your advice as to whom to consult there; you take the "Directory" and look up the various practitioners in that town, but can form no idea of the men; except that Dr. A. graduated at such a college in such a year. If, however, you could see among them, So-and-So M.D., Harvard, '84, H.G.s. St. Luke's, '86, you would know that he is probably the best man to whom to send a surgical case; or if H.G.M., a medical case. Or, if we see So-and-So, M.D., Physicians and Surgeons, '84, H.G.s. Woman's Hospital, we know that of course, he is the best man to whom to send a gynecological case. The title of H.G., "Hospital Graduate," if adopted, would represent a preparatory fitting in study, experience, manual dexterity, and in all other respects of far greater value to the community than does the average undergraduate course with its M.D., and very often of greater value than five or ten years of general practice. Adding to this indication of H.G. the letter S. for surgical, or M. for medical, would inform one of the nature of his preparatory work; and adding the name of the hospital would still further indicate the character of his experience.

It is but just that these men should have credit for work done. It will be useful to the profession desiring consultation and co-operation, and thus, through the profession, of great advantage to the community, that there be some way of ascertaining these specially trained men.

Moreover, it will be one means of lifting the standard of medical education, and will give a greater stimulus for a hospital training and experience, which is already gaining in value year by year.

Is not the adoption of such titles in our own hands? No legal steps seem to be required. All that appears necessary is that we should by common consent append to our names the abbreviation of H.G.S., or M.—surgical or medical—with the name of the hospital, in the medical registers, directories, etc.

It would be of great service to us if the medical boards of our various hospitals would give official sanction and secure a legal right to such titles. They should be authorized to grant diplomas, as is customary by colleges, or should specify such titles in the certificates or diplomas which they now issue, thus making the hospital course of greater value. If they are advised by their counsel that any legislation is necessary to authorize such a usage, we would earnestly request that they should take steps to procure it. United action in this matter would establish the usage permanently, to the advantage of every hospital alumnus and the medical profession.

I therefore ask of you as Alumni of the Woman's Hospital, that I may have your endorsement to this letter to hospital graduates, if, upon discussion, you favor my plea for the degree of H.G.S. and H.G.M.

The undersigned were appointed a committee of two to take further steps in the matter. They will be glad to receive suggestions pro and con. from hospital graduates and others, with reference to the subject.

Dr. Sherman Van Ness, 91 Madison Avenue,
Dr. George E. Abbott, 19 East Sixty-first Street.

Progress of Medical Science.

The Cœliac Affection in Children.—The abdominal affections of children are, notwithstanding much good work that has been done in recent years, still involved in a good deal of obscurity, not to say confusion, and we therefore feel especially indebted to Dr. R. A. Gibbons for his paper, with the above heading, in the *Edinburgh Medical Journal* for October and November, in which he gives a concise and lucid description of a malady which has hitherto almost entirely escaped separate recognition. The title he has chosen means, as he is careful to explain, nothing more than that the affection is one of the abdomen, and involves no theory as to its causation or pathology; it was used by Dr. Gee two years ago, in a lecture at the Hospital for Sick Children, Great Ormond Street, London, and subsequently in a paper published in the "St. Bartholomew's Hospital Reports." The malady is one which, without being at all common, is by no means unknown, and many practitioners of large experience will, on reading the description of Dr. Gibbons, be able to recall one or more instances of it. The disease is characterized by the passage of large, loose, white or whitish, frothy, intensely fetid motions; it is an affection of early life, occurring in children under five years of age. The onset is gradual and insidious, pallor and general debility being the most noticeable symptoms. The fetid character of the motions is sometimes the first indication that there is anything wrong with the child; the motions resemble oatmeal porridge, or, as a mother said to the writer not long since, the motions are "exactly like the Chapman's flour he is taking;" generally there is only one action of the bowels a day, but that is extremely copious; there may be two or even three stools daily, and occasional attacks of diarrhœa are not uncommon. The appetite is poor or capricious, abdominal pain is often complained of, the abdomen is generally soft and doughy, the liver may be just palpable, the spleen is not as a rule enlarged, and no enlarged abdominal glands can be felt. Anæmia and great debility are usually very marked features, the child being incapable of any exertion; but, as a rule, there is no wasting; the flesh, however, is not firm as in health, but soft and flabby. The malady is a very serious one, as the children are very liable to die from mere exhaustion, or to be carried off by an intercurrent watery diarrhœa, and relapses are exceedingly prone to occur. Improvement, as a rule, first shows itself in a healthier condition of the

evacuations. The prognosis must, therefore, always be grave, and will depend upon the means and intelligence of the parents, and their ability to carry out all the directions as regards diet, which are so essential for the child's recovery. Nothing is known as to the pathology; no constant changes have been found upon examination after death, either with or without the microscope, nor has microscopical examination of the motions or blood during life added anything to our knowledge of the disease. In treatment, the most scrupulous attention to every detail of diet is essential. Cow's milk must be forbidden, owing to the insoluble character of its casein, and ass's milk should be substituted; cream may be given mixed with scalded whey prepared from cow's milk. For the principal meal, pounded raw meat should be used, either beefsteak or mutton, it matters not which; it should be freed from skin and fat, cut up, finely pounded in a mortar, and rubbed through a hair sieve. It should be given with a little sifted sugar or fruit jelly and a pinch of salt; the amount will vary from one to four tablespoonfuls, according to the age of the child; if this is not well borne, the juice extracted from the raw meat by hydrochloric acid should be given. Plain biscuits or rusks with plenty of fresh butter may be allowed, and a little floury potato; malted foods will also sometimes be found useful. The hygienic surroundings of the child should be carefully attended to, and he should be clothed entirely in silk or wool. As regards drugs, Dr. Gibbons places great reliance on bismuth with compound tincture of camphor, or the compound kino powder for attacks of watery diarrhœa; when there is vomiting as well as diarrhœa, he recommends minute doses of gray powder. The explanation which Dr. Gibbons offers of these cases is very plausible, though, as its author freely admits, it is at present purely theoretical; it is that the secretions of the liver and pancreas and the intestinal juices are deficient. A diminished supply of bile is quite consistent with the colorless character of the stools and with their fetor, for, as is well known, the bile is a great antiseptic; the fermentation which they are thus permitted to undergo in the alimentary canal will fully account for their extraordinary bulk. A deficiency in the pancreatic juice would probably have the same effect, and it is consonant with this theory that starchy foods are exceedingly badly borne by the sufferers from this disease. Dr. Gibbons therefore suggests that owing to some unknown influence acting through the nervous system, there is inhibition of the secretions of the liver and pancreas, and probably also of the glands of Brunner and follicles of Lieberkühn, the result being the production of the motions which are characteristic of this disease.—*The British Medical Journal.*

Rectal Administration of Iodide of Potassium.—Professor Köbner has found this form of application useful in two directions, (1) locally, and (2) constitutionally, where the drug exerts its influence on distant organs as well. For many years the iodide has been in use in the form of suppository in chronic prostatitis, some employing it as an inunction into the rectal mucous membrane by means of the finger. The dose usually given for this purpose is three grains to the suppository. To this Köbner has added other substances. Thus, where there was considerable sensitiveness, or a lobe of the prostate painful, or reflex tenesmus present, extract of belladonna (gr. ½) once a day, or bromide of potassium (gr. 4) was of great assistance. Where the suppository was rejected in consequence of irritability of the mucous membrane, small enemata of iodide with bromide, if necessary, or, in cases of obstinate prostatic affection, pure tincture of iodine, nine to ten drops, were substituted. The local application was likewise useful in syphilitic intestinal ulcers with profuse secretion from the rectal mucous membrane. The rapidity with which the iodide appeared in the saliva and urine in these prostatic cases showed its absorption from the intestine to be almost as ready as when given by the mouth, and suggested this method of administration where constitutional effects are desired, for instance, in syphilis. Such a proceeding was therefore adopted in a case where the least trace of iodide by the stomach produced very severe iodism, rendering the continuation of the drug unbearable. The result was satisfactory, fifteen-grain doses being borne with complete success. This method was also found valuable in cases of syphilis where a large amount of iodide was required to be introduced rapidly, and in syphilis of the brain where difficulty of swallowing existed.—*Therapeutische Monatshefte.*

A New Method of Treatment in Prolapse of the Rectum.—M. Verneuil, at the Société de Chirurgie, described a new method of treating rectal prolapsus, by attaching the adhesions of the posterior surface of the rectum to the corresponding portion of the pelvis (*The British Medical Journal*). After reducing the intestine the portion of the anal orifice to be excised is determined. A triangular fragment is then traced by means of two transverse incisions passing through the posterior portion of the anal orifice, and two others passing from the extremities of the two first to the point of the coccyx. When the rectum is exposed four Florence horsehairs are introduced into its wall, and placed at intervals of 1½ ctm. from each other. The intestine is raised by drawing all the threads toward the concave portion of the sacrum. In order to fix the intestine permanently the threads are drawn through the skin to the right and left of the wound, at 4 ctm. distant from the median line, with Emmet's needle. Thus four handles in the form of a **U** are contrived, which may be tightened at will. The fragment traced as above described is then detached at the base. The ano-coccygeal wound is closed by transverse sutures. A large drain is placed at the back of the rectum, in order to form a track which will sustain and increase the adhesions. The anal orifice is contracted by suture with Florence horsehair. M. Verneuil obtained good results, in a case which had lasted four months, with this method, which he names "posterior rectopexia." At the same meeting M. Delens recommended the following method in cases of voluminous prolapsus. He applies fuming nitric acid to the tumor, reduces and plugs the anus, and administers opium in order to prevent the occurrence of stools during at least eight days. M. Schwartz has obtained good results by making scores with the thermo-cautery on the projecting intestine, and pushing backward the anus toward the coccyx, the old orifice being closed by perineorrhaphy. M. Segond considers that ablation should be practised in order to perform colopexia with success.

A New Heart Disease.—The Paris correspondent of the *British Medical Journal* writes: "M. Renaut, in a paper sent to the Academy of Medicine, describes a new form of cardiac lesion which he terms 'myocardite segmentaire essentielle.' It is a special form of lesion of the muscular cardiac tissue, most frequently met with among old people, especially those who are prematurely senile, likewise among drunkards. The fibres become separated, owing to degeneration of the connective tissue which unites the bundles; the substance of the muscular fibre is also attacked. The heart is not hypertrophied, nor is there fatty degeneration or arterial sclerosis, the myocardium is of gray color. The necropsy shows that the left ventricle is flattened. The sphygmographic tracings are not those of other known cardiac affections. The symptoms are œdema of the ankles, stasis, and pulmonary congestions, which should be treated by digitalis and ergot of rye."

The Open-Window Treatment of Phthisis, as recommended by Detweiler, has recently received the attention and commendation of a French physician, M. Nicaisen, who has tried it. He states that with open windows, when the out-door temperature ranges from 28° to 58° F., the air in his room ranged only from 52° to 62° F.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, April 5, 1890.

SANITATION ON OCEAN STEAMSHIPS.

We referred recently to the strange indifference of the managers of the various steamship lines to the health of their patrons, so plainly manifested by their neglect to provide a satisfactory medical service on their vessels. The companies have no excuse to offer for this neglect, and they can have none, for the remedy is wholly within their own hands. There are competent men enough to fill these positions, but they are apparently not wanted, for if they were there would be some inducement held out to them to come.

But it would not be sufficient to secure competent surgeons—they should also be entrusted with the control of sanitary matters in the vessel. And then there should be suitable provision for the care of the sick and the isolation of those with contagious disease. There are supposed to be hospitals on every ship, but unfortunately these are not infrequently diverted to other purposes, so that, when needed, they are found to be unavailable. Mr. Charles H. Leet, formerly a surgeon in the employ of one of the transatlantic steamship companies, has published a pamphlet in which he relates some flagrant instances of disregard of the law relating to the ship's hospitals by the officers of the vessel. On one occasion the female infectious hospital had been illegally occupied, and Dr. Leet was in consequence forced to put a Sister of Mercy, ill of measles, in the male hospital, which was leaky, and where the patient was forced to listen to the ribald conversation of the men bunking close to the hospital under the forward turtle-back. At another time the purser occupied one of the hospitals, having let his own room to a passenger. These instances occurred in 1886, and it might be thought that perhaps such abuses no longer existed. But in a letter written to *Seafaring*, a nautical journal published in Liverpool, under date of February 22, 1890, Dr. Leet shows that there is still room for reform, for in 1889 the hospital on one ship was used for steerage passengers on the western trip, and sick women had to be treated in their own berths and under the most unfavorable circumstances.

That this misappropriation of the ship's hospitals is not discouraged by the company is shown by an official order stating that "the hospitals are to be under the surgeon's charge only when occupied by patients, at which time he will be responsible for their cleanliness and proper ventilation. When unoccupied they are to be at the captain's disposal." It is the boast of the managers of one of the largest of the transatlantic lines that they have never lost a life by accident at sea. Have they never lost a life by disregard of sanitary measures at sea? If not, they are to be congratulated upon their exceptional good luck. During the coming summer there will be many physicians crossing the Atlantic to be present at the International Congress in Berlin, and they could not employ their leisure while at sea in a more useful way than in investigating for themselves the question of ship sanitation, and in noting how nearly the officers of the vessel upon which they may be sailing comply with the law regulating hospitals and air space in the cabins and steerage. That the law is evaded in numerous instances there can be no question, and since the majority of ocean travellers are either Americans or emigrants intending to become Americans, it closely concerns us to see that such violations of sanitary rules shall not occur. It is both unpatriotic and criminal to suffer the health and the lives of Americans to be jeopardized for nothing better than to fill British pockets.

HOW IT LOOKS TO AN OUTSIDER.

Familiarity does not always breed contempt, but it sometimes blunts our sense of the ludicrous, and prevents us from seeing anything out of the way in what to a stranger may seem most comical. We are so accustomed to the ways of the average dispensary official, and to his eagerness to extend the sphere of usefulness of his institution (in order to please the old subscribers to the "charity" and to attract new ones) that, although we may deplore the injury he does to his brother physicians, as well as to the poor whom his dispensary is supposed to help, we do not always see the funny side of it. But a stranger, to whom such doings are a novelty, looks upon them in a somewhat different light and sees the ridiculous as well as the more serious side.

Dr. O. B. Will recently entertained the Peoria City Medical Society with an account of what he saw and heard during a visit to New York. He was very well pleased with his trip, and said many complimentary things of us, but he could not help telling of an absurd chase after a woman who was so fortunate as to have a rare affection of the cervix uteri. She put in an appearance, he said, at one of the clinics; but as "the case was an interesting one, before the necessary operative procedure was resorted to, it was determined to make a drawing of the parts for publication, and to that end the patient was requested to call the next day. In the meantime, however, the authorities of other hospitals heard of it, and solicitors from no less than three rival institutions were sent to her. One of them succeeded in prevailing upon her to go to his favorite, and they actually sent a carriage for her and carried her off in triumph, and withal in regal style."

Comment on the above is hardly needed, but we will see how it struck Dr. Will, so that we may the better learn how we look to our visitors. "To the average man," he says, "professional or non-professional, such actions seem ridiculous, and unworthy the connivance of a self-respecting surgeon. And yet, what is one going to do about it? In a city where large sums are expended annually by members of the profession in search of such

knowledge, there is bound to be the keenest competition in supplying the demand, and to that end patients are an absolute necessity. It is in its tendencies unquestionably vastly demoralizing to both the profession and the public, virtually paying, as it does, a premium on dishonesty and thriftlessness, and depriving deserving younger and less notable practitioners of moderate fees which many of those who avail themselves of these clinical advantages are abundantly able to pay. The fact is, that it is almost impossible any more for a man to secure a practice in the city of New York, in an ordinary lifetime, without either associating himself with some established practitioner, or first connecting himself in some menial capacity with one of the many clinics or dispensaries, and thus gradually, through many years of toil, work himself into acquaintanceship with those whose independence of feeling will not permit them to seek the aid of public charity."

THE BEST STETHOSCOPE.

Very little advance has been made in stethoscopes since the year 1852, when Dr. Cammann, of this city, perfected his binaural instrument. This is beyond all question the most serviceable form of stethoscope; it has become almost universally adopted in America, and it is much used in England.

In a recent article by Dr. P. K. Pel, of Amsterdam, entitled, "What Stethoscope should the Physician Use?" (*Berlin. klin. Wochenschrift*), the various forms of this instrument are discussed, and the conclusion reached that the binaural stethoscope of Cammann is the best. He deplores the fact that it is yet unknown, or not used, in Germany. We trust that Dr. Pel's article will promote the spread of the American stethoscope.

COLUMBUS AND SYPHILIS.

The forthcoming celebration of the discovery of America by Columbus will doubtless give rise to queries from cynical philosophers as to whether this discovery was really so supreme a good to mankind. America is still regarded as an uncultured province by many more or less lettered Europeans, and one of them has asserted that after subtracting tobacco and quinine it would be difficult to find any essential good that has come from the Western Hemisphere. But of all the indictments which could possibly be drawn against the new continent, none could be seriously considered beside that of its having infected the rest of the world with syphilis.

Two facts are believed to be reasonably well established in this connection, viz., that syphilis existed in America before Columbus discovered it, and that syphilis first became widely spread and noticed in the latter part of the fifteenth and early part of the sixteenth century.

The general belief has been, and is now, that syphilis existed in a quiescent form before this period in the southern portions of Europe. But it has seemed difficult to understand why syphilis should have been quiescent up to A.D. 1494, while it has never been so in the four hundred years since that time.

The existence of a pre-Columbian syphilis has been denied by Dr. J. P. MacLean (*American Medical Journal*, August, 1884); but lately has been learnedly affirmed by Dr. Gust. Brühl (*Cincinnati Lancet and Clinic*, March 8, 1890), who says, among other things, that among the Mexican Indians there are seventeen different names for syphilis.

It is probable that we shall never reach a certainty with regard to this question.

It may be borne in mind, however, that, heretofore, almost all the students of this problem have been Europeans, possessed with a little natural bias in favor of the American origin of the disease.

It is estimated that in cities one out of every fifty or sixty persons has syphilis or has had it. The amount of pain, misery, and sorrow caused by this disorder, and its pernicious hereditary effects, all combine to make it far the worst scourge which has ever been placed upon humanity. If Columbus were responsible for the syphilitic millions of the last four hundred years, we would feel that the glory of his magnificent achievements was sadly dimmed.

THE HOT SPRINGS OF ARKANSAS.

The Hot Springs of Arkansas have acquired a very wide reputation for the relief of syphilis and rheumatism. This repute of the Springs, however, is much better among the laity than among the physicians in general. There is a well-defined belief, for one thing, that the commercial side of the practice of medicine reaches its highest development at this resort, and that the physicians there do not, as a rule, possess scientific attainments, or more than a very narrow technical skill. It is quite agreed also that the waters there have no medicinal properties apart from their temperature.

Nevertheless, there must be some fire where there is so much smoke; and we have read with much interest the discussion on the value of the Hot Springs treatment which recently took place before the Dermatological Society of this city. The speakers included Drs. E. L. Keyes, J. A. Fordyce, P. A. Morrow, Piffard, Bronson, Allen, Bulkley, and others.

The weight of opinion seemed to be that the Hot Springs did not answer in the second stage of syphilis; that in the third stage, when the patients were cachectic and anæmic so that they could not take large doses of mercury and iodide at home, a sojourn at the Springs might be efficacious. Even then, however, the treatment, which is heroic, is one that is not always without danger.

Some of the speakers thought that, by the use of hot baths and hot drinks at home, just as good results could be accomplished as in Arkansas.

ANEURISMS IN CHILDHOOD.

There are certain diseases which are interesting because they are rare, and others because they are frequent. Among the former class belong aneurisms in children. Dr. A. Jacobi publishes an article upon this subject in the *Archives of Pediatrics* for March. This article, though exhaustive, is nevertheless short, for it appears that only twenty-nine cases of extracranial aneurism in early life have been reported, the last being one by Dr. Lehlbach, of Newark, N. J., and published in Dr. Jacobi's article.

It seems that the causes of aneurism in childhood are almost as numerous as the cases. In Dr. Lehlbach's

case the trouble was apparently due to tubercular infection; in other instances it has been due to abscess, embolism, endarteritis, congenital incompetency of the walls of the blood-vessels, and hyaline degeneration of the vessel-walls.

Aneurisms in childhood affect the cardiac and pulmonary vessels as well as the aorta; they are sometimes multiple, and generally do not reach a large size.

On the whole, it appears that aneurisms in childhood are almost always symptomatic of some serious local or constitutional disorder, such as tuberculosis or cardiac disease. They do not often develop as single dilatations, running a chronic course and acting as the chief focus of disease and the dominant cause of the morbid symptoms.

ENLARGEMENT OF THE MEDICAL PART OF THE PENSION BUREAU.

A BILL has passed the United States House of Representatives providing for the appointment of thirty more medical examiners in the Pension Bureau. These appointments are to be made without regard to the Civil Service Rules.

The enlargement of the medical force of the Pension Bureau is much needed, as we have already called attention to this fact. The placing a part of the appointments under the Civil Service Rules and part under the "spoils" method is much to be deprecated. Already much criticism has been aroused by the character of the appointments in some places; the medical part of the Pension Service ought to be composed of reputable medical men, not of political "docs."

News of the Week.

Dr. Frederick J. Leviseur has been appointed Visiting Dermatologist to the Randall's Island Hospitals.

Convicted for Pretending to Conduct a Hospital.—Dr. Theodore S. Wilcox, an octogenarian who ran a boarding-house in Brooklyn, and under the name of the Sanitarium Hospital and Dispensary had fraudulently got $1,726.55 from the excise funds, was convicted recently, and received a mild punishment in view of his years.

Prize for Physiological Work.—A member of the American Physiological Society has offered $250 for the best research or researches bearing on the subject stated below, viz.: "The regeneration of several spinal nerves in mammals, including man, with special reference 1, to the reunion and return of function in such severed nerves, without degeneration of the distal portion; 2, to the possibility of union, with return of function, between the central portion of any one spinal nerve and the distal portion of any other (*e.g.*, the central portion of the ulnar with the distal portion of the median)." Conclusions to be supported, so far as possible, by histological as well as physiological evidence. The competition is limited to residents of North America, and the prize will be awarded for original work done after January 1, 1890. The award will be made by those persons who on October 1, 1891, constitute the Council of the American Physiological Society. For the present, communications concerning prize should be addressed to H. Newell Martin, Secretary, Johns Hopkins University, Baltimore, Md.

Dr. William H. Triplett, a prominent physician and surgeon, died at Woodstock, Va., March 27th, at the age of fifty-three. For a time he resided at Washington, D.C., and London, England.

Association of American Physicians.—Preliminary programme of the Fifth Annual Meeting of the Association of American Physicians, to be held at the Army Medical Museum Building, Washington, D.C., on May 13, 14, and 15, 1890: The President's Inaugural Address, Samuel C. Busey, Washington, D.C. Consideration of the Revised Constitution. *Discussions:* "Disturbances of Sleep," Referee, S. Weir Mitchell, Philadelphia, Pa.; Co-referee, Charles F. Folsom, Boston, Mass. "Methods of Diagnosis in Diseases of the Stomach," Referee, Francis P. Kinnicutt, New York, N. Y.; Co-referee, F. C. Shattuck, Boston, Mass. *Papers:* "Inflammations of the Appendix and Cæcum and the Duty of the Physician Regarding Them," by Norman Bridge, Chicago, Ill.; "Anæsthetic and Non-Anæsthetic Hysteria," by Charles L. Dana, New York, N. Y.; "Seizures Characterized by Shock and Loss of Consciousness," by Israel T. Dana, Portland, Me.; "The Diathetic Causes of Renal Inadequacy," by I. N. Danforth, Chicago, Ill.; "Antisepsis in Midwifery," by William T. Lusk, New York, N. Y.; "Varicose Aneurism of the Arch of the Aorta," by William Pepper and J. P. C. Griffith, Philadelphia, Pa.; "Natural History of Typhoid Fever," by James E. Reeves, Chattanooga, Tenn.; "What Can and Should be Done to Limit the Prevalence of Tuberculosis in Man?" by Edward O. Shakespeare, Philadelphia, Pa.; "Migraine," by Wharton Sinkler, Philadelphia, Pa.; "Etiology of Pleurisy, Especially in its Relation to Tuberculosis," by A. A. Smith, New York, N. Y.; "Report of Cases of Angio-Neurotic Œdema," by Samuel B. Ward, Albany, N. Y.; "Notes of a Case of Acromegaly," by J. E. Graham, Toronto, Can.; "A Case of Acute Pancreatitis," by R. H. Fitz, Boston, Mass.; "Demonstration of Pathological Specimens," by W. T. Councilman, Baltimore, Md. Those who are to contribute papers may send to the Secretary, Dr. Henry Hun, 33 Elk Street, Albany, N. Y., the names of members whom they wish to have invited to participate in the discussion; and by sending their papers to the Recorder, Dr. I. Minis Hays, 266 South Twenty first Street, Philadelphia, Pa., as early as possible and at a reasonable time prior to the meeting, they can receive five or six copies in type, which they can forward to those members whom they wish to have participate in the discussion. There will probably be time at the meeting for the reading of two or three papers more than those on this programme. Members who desire to contribute such papers are requested to send the titles of them to the Secretary. The constitution provides that papers shall not exceed twenty minutes in the reading.

The State Care of the Insane.—The bill for the care of the insane in State asylums as against county poor-houses has as last passed the Senate, to the great joy of every citizen not interested in jobbing county politics. The proper place for the treatment of the insane is in a well-equipped State hospital—in a poor house, never!

How to Describe a Medical College Commencement.—We submit the following for use by esteemed contemporaries in writing up medical college commencements. It can be cut out, the blanks filled in and used indefinitely: "The closing exercises of that now widely famous institution, the —— —— Medical College, were celebrated with unusual brilliancy and success on —— —— The graduating class was very large, and it was generally agreed to be one of unusual talent and of remarkable professional promise and physical appearance. The fine, manly appearance of the young men, as they received their diplomas and bouquets, excited much enthusiasm among the ladies. The Hall was expensively decorated with rare exotics, whose odors, mingling with the eloquence of the orators and the music of the string band, aroused the profoundest sensations of delight among the audience. The opening prayer by Rev. —— —— was a burst of devotional eloquence, and the address to the class by the orator of the evening, Hon. —— ——, was filled with felicitous thoughts, beautiful and appropriate imagery, and quite brought down the house. The address in full appears on p. ——. The sentiments of the valedictory were singularly fitted to the occasion, and evidently much affected the eminent professors, who were thus to lose so many devoted pupils. The exercises closed with a stirring march from the band and the benediction. Altogether the occasion is one long to be remembered by the participants. Long may the —— —— Medical College flourish in its noble work!" No copyright.

Kansas City Medical College held its annual commencement March 10th, and conferred diplomas upon a class of sixteen.

The University of Nashville, Medical Department, held its annual commencement February 26th, and graduated a class of 138 students.

Two Failures of the Pasteur Treatment have recently been reported.

Doctor's Daughters as Servants.—A writer upon "Educated Women of the Upper Classes as Servants," in an evening paper interviewed an unnamed person on the subject, and elicited the following: "My servants are now always ladies," says gossip to gossip. "I have one a housemaid, a charming girl, who is the daughter of a *medical man*, and all of whose male relations are professional men, and who does her work as thoroughly and as well as any ordinary servant could be expected to do it."—*Hospital Gazette.*

The McKinley Tariff Bill has some features that will interest medical men. It allows the importation free of books and pamphlets printed in any language but the English, and of periodicals in all languages. Opium is put upon the free list.

Recognition of Veterinarians.—The French Government, says *The Journal of Comparative Medicine*, by a decree of the Minister of Agriculture, has ordered that the holders of the diplomas given by the American Veterinary College may be, by virtue of this diploma, authorized to compete for the French diploma after having passed in one of their schools the time assigned to them, according to their degree of instruction, by the council of professors in the school in which they wish to follow their course.

American Medical Association.—A meeting of the general committee of arrangements for the meeting of the American Medical Association was held in Nashville on the evening of March 20th. It was decided to have a general social entertainment at the Capitol, May 20th, the day on which the association convenes, in order that the visitors and citizens may meet and become acquainted. Dr. Morgan, secretary of the committee on halls, hotels, etc., reported the work of the committee complete, and that the hotels would be able to accommodate two thousand five hundred delegates. The general association meetings will be held at the Vendome in the forenoons, and the section meetings will be held in the afternoon in various halls throughout the city. The Medical Editors' Association will meet in annual session May 19th, in the lecture room of the Dental Department of Vanderbilt University. The prospects were reported flattering for a full meeting of the association. It is thought that there will be between two and three thousand visiting physicians present.

Bicycling for Young People.—Dr. B. W. Richardson discusses this subject in a recent issue of the *Æsclepiad.* He admits that since he first warned the public of the dangers of immoderate cycling, changes have taken place in the construction both of bicycles and tricycles which materially modify the old drawbacks. He is still, however, of opinion that cycling should never be practised by boys and girls, since it differs from other exercises in the fact that it molds the bodily framework, as it were, to its own mode of motion; and riders in course of time almost invariably acquire what he calls "the cyclist's figure," which is not graceful, and is not indicative of the possession of perfectly balanced powers. Of two things at least he is satisfied. They are that the temptation of competition is to an earnest and practised cyclist a "demon of danger," and that the systematic pursuit of cycling should never be fully commenced before the age of twenty-one.

Night Medical Service in Paris.—During the year 1889 the total number of patients seen by the members of the Paris Night Medical Service was 8,544, as against 7,408 in 1888. Of this number 2,684 were men, 4,339 women, and 1,521 children. In the month of December, when the influenza epidemic was at its height, the number of patients seen was 1,250.

The Thumb and Lunacy.—The following is an interesting specimen of the rubbish that circulates as "popular science" in the columns of the daily papers. The *Philadelphia North American* says: A physician in charge of a well-known asylum for the care of the insane recently said to the writer: "There is one infallible test either for the approach or the presence of lunacy. If the person whose case is being examined is seen to make no use of his thumb, if he lets it stand out at right angles from the hand, and employs it neither in salutation, writing, nor any other manual exercise, you may set it down as a fact that that person's mental balance is gone. He or she may converse intelligently, may in every respect be guarding the secret of a mind diseased with the utmost care and cunning, but the tell-tale thumb will infallibly betray the lurking madness which is concealed behind a plausible demeanor."

Cremation in Paris.—The practice of cremation is so largely on the increase that it has been decided to build a new furnace at the cemetery of Père-la-Chaise, Paris. The furnace at present in use is kept burning night and day, a system which permits of the complete destruction of the corpse in less than an hour.

The Late Professor Volkmann's "Sammlung Klinischer Vorträge" is to be continued under the direction of V. Bergmann, Erb, and Winckel.

A Verdict for the Surgeon.—"Physicians in the western part of Massachusetts," says the *Boston Medical and Surgical Journal*, "are much interested in the case lately tried in Springfield, of Homer C. Ross against Dr. Wallace H. Dean, of Blandford. The plaintiff asserted that he had lost the use of an arm because it was improperly set by Dr. Dean after it was broken in an accident. But the best-known doctors of the vicinity testified that the treatment was all right and that the arm could be used. Dr. Francis Bacon, of New Haven, extended the man's arms and held them up for a time, when he suddenly stopped supporting them. The fact that they remained extended long enough to exhibit the absence of paralysis was conclusive. The result was that Judge Barker instructed the jury to bring in a verdict for Dr. Dean without leaving their seats."

M. Pasteur and the Rabbit Pest in Australia.—In respect to a statement alleging that the Australian Government had refused to allow M. Pasteur the reward of £20,000 offered to the person who should suggest the best plan for the destruction of the rabbits that infest that colony, M. Pasteur is reported to have said that this was not so, for the simple reason that he had never sought it, and that, owing to circumstances over which he had no control, he could not claim such a reward. He had sent M. Loir, his nephew, and another of his assistants to Australia in order to try the experiments which he had made in his laboratory on a more extended scale. The assistants returned to France after a few months, discouraged. According to M. Pasteur, they were not allowed by the Commission appointed by the Australian Government to make any important experiments. This Commission permitted the assistants to inoculate a few rabbits, and the experiments were successful enough to warrant a further extension of the authorization; but all sorts of delays and adjournments were caused, until the assistants abandoned all hope of being able to carry out the purpose for which they had undertaken the voyage to Australia.—*British Medical Journal.*

International Medical Congress, Section on Obstetrics and Gynecology.—The Committee of Organization for the Section of Obstetrics and Gynecology consists of Professors Fritsch (Breslau), Gusserow (Berlin), Hegar (Freiburg), Hofmeier (Würzburg), Kaltenbach (Halle), Löhlein (Giessen), Martin (Berlin), Olshausen (Berlin), and Winckel (Munich). The following subjects are proposed for the morning meetings (10 to 1): 1. "Antisepsis in Midwifery;" introduced by Galabin (London); discussed by Stadfeldt (Copenhagen), Slavijanski (St. Petersburg), Fritsch (Breslau). 2. "Artificial Premature Labor, its indications and methods;" introduced by T. Parvin (Philadelphia); discussed by Calderini (Parma), Macan (Dublin), Dohrn (Königsberg). 3. "Vaginal Extirpation of the Uterus;" introduced by Williams (London); discussed by Pozzi (Paris), Schauta (Prague), Olshausen (Berlin). 4. "Electrolysis of Myoma;" introduced by Apostoli (Paris); discussed by T. Keith (London), E. Cutter (New York), Zweifel (Leipzig).

Women's Opportunities in Belgium.—On January 30th the Chamber of Representatives, acting in concert with the Ministry, passed an enactment that henceforth all university lectures and courses of instruction, together with all academical degrees, shall be open to women. Moreover, whereas they have hitherto only been allowed to practise certain branches of the healing art, both medicine and pharmacy are now thrown open to them without restriction.

The Riberi Prize of Twenty Thousand Francs has been given by the Academy of Medicine of Turin to Professor His, for his embryological studies.

The National Association of Railway Surgeons holds its third annual meeting in Kansas City, Mo., May 1, 1890.

Attacking Vivisection Again.—The last issue of *The Forum* contains an article by one Dr. Caroline White, attacking the practice of vivisection. The author says nothing new, and supports her opinions by statements which are, as a rule, either unsubstantiated or totally false. The article does not appear to us to deserve serious consideration.

At the Pasteur Institute in this city it is stated that already three persons, who are supposed to have been bitten by rabid dogs, have been inoculated.

Meetings of State Medical Societies.—The annual meetings of State Medical Societies are announced as follows (*New York Meaical Journal*): Alabama, Birmingham, April 8th; Florida, Ocala, April 8th; Tennessee, Memphis, April 8th; California, Los Angeles, April 15th; Georgia, Brunswick, April 16th; Iowa, Des Moines, April 16th; Mississippi, Jackson, April 21st; Maryland, Baltimore, April 22d; Texas, Fort Worth, April 22d; South Carolina, Laurens, April 30th; Illinois, Chicago, May 6th; Kansas, Salina, May 13th; Louisiana, Baton Rouge, May 13th; Nebraska, Beatrice, May 13th; Arkansas, Little Rock, May 14th; Indiana, Indianapolis, May 14th; Kentucky, Henderson, May 14th; Washington, Spokane Falls, May 14th; Michigan, Grand Rapids, May 20th; Missouri, Excelsior Springs, May 20th; North Carolina, Oxford, May 27th; Connecticut, New Haven, May 28th; Ohio, Columbus, June 3d; Wisconsin, Milwaukee, June 4th; Delaware, Wilmington, June 10; Maine, Portland, June 10th; Massachusetts, Boston, June 10th; New Jersey, Schooley's Mountain, June 10th; Pennsylvania, Philadelphia, June 10th; Dakota, Sioux Falls, June 12th; Rhode Island, Providence, June 12th; New Hampshire, Concord, June 16th; Colorado, Denver, June 17th; Minnesota, St. Paul, June 19th; Vermont, Rutland, June 26th (semi-annual); Virginia, Rockbridge Alum Springs (to be announced); Vermont, Montpelier (annual), October 9th; New York (State Medical Association), New York, October 22d. The American Medical Association meets at Nashville, Tenn., on May 20th to 23d. Announcements of the Oregon and West Virginia Societies have not been received.

Women Physicians in India.—At a meeting of the Alumnæ Association of Rutgers' Female College, held recently in this city, Dr. Jessie B. Woodside delivered an interesting lecture upon the aspects of medical missionary work among the women of Hindoostan. Dr. Woodside has lived in India, practising as a medical missionary, for three years.

International Medical Congress. — The Hamburg-American Packet Company has issued a circular announcing special rates for physicians attending the Tenth International Medical Congress. On the express steamers sailing July 17th and 24th, the rates for the round trip will be $150 to $200; on the Wieland, sailing July 19th, the rate will be from $90 to $126 for the round trip, and on other vessels of the regular service sailing prior to this date the rates are $93.50 to $127.50. The Congress will be held on August 4–9, 1890.

An Unusual Colorado Winter.—The past winter in Colorado has been a surprise to the older residents of the State. The rains of November, succeeded by snow in December, and the paucity of clear days, have caused misgivings lest the type of the climate shall be changing from dry to humid, and from bright to dismal.—*Journal of American Medical Association.*

Dr. Edwin Arius Kilbourne, Superintendent of the Illinois Northern Hospital for the Insane at Elgin, died February 27, 1890, at that place, in the fifty-third year of life.

Iodide of Sodium and Iodide of Potassium.—Dr. Laborde, of Paris, has just read a memoir before the Academy of Medicine, in which he contends that iodide of sodium has a different action from iodide of potassium and cannot be properly substituted for it. Iodide of potassium augments the blood-pressure while the sodium compound scarcely modifies it. Iodide of potassium has a convulsive action also which the iodide of sodium does not.

Monument to Dr. Philippe Ricord. —A committee has just been organized, under the presidency of Professor A. Fournier, with the view of raising a monument to the memory of the late Dr. Philippe Ricord.

A Philadelphia Physician in Africa.—Dr. W. L. Abbot, of Philadelphia, has recently arrived at Zanzibar, from the interior of East Africa, where he has been engaged in making explorations and scientific collections, some of which are for the Smithsonian cabinets. The most frequent ailment which Dr. Abbot was called on to treat was leg ulcer.

The Origin of Typhoid Fever.—Dr. Uovo, and Messrs. Rodet and Roux have made a series of bacteriological studies leading them to the conclusion that the bacillus of typhoid fever is only the bacillus coli communis, rendered virulent by influences outside the body. They believe, therefore, that water contaminated by fecal matter not necessarily typhoidal may give rise to typhoid fever.

The Brooklyn Institute.—A new section, to be known as the department of psychology, has been formed in the Brooklyn Institute, the purposes of which are the consideration and discussion of ethical and philosophical questions. Clergymen and physicians are expected to make up the greater part of the membership.

"**Rachilysis**" is the name given by Mr. Barwell to his method of treating spinal curvature. It is described as follows: At the sides of the room he fitted an arrangement of rings and hooks from which the force worked. One padded band with loop attached was placed on the apex of the lumbar curve. The patient was inclined over against the restraint of the band until that curve was annulled or reversed, and the trunk was held in that position by a lanyard under the left axilla. Another belt, with the loop in the contrary direction, was placed on the apex of the dorsal curve. A system of pulleys was hitched to the loop, a wooden strut being placed between the laps of each band so as to prevent constriction. Mr. Barwell showed the action of his appliance on two boys from the Cripples' Home in Kensington, pointing out how their backs became straighter, and that the process was quite painless.

A New Hospital in Omaha.—Ground has been purchased in Omaha, Neb., by Bishop Newman of the Methodist Church, for the erection of a hospital. There are at present but two hospitals in that city—St. Joseph's and the Childs—although a third is building.

Regulating Fees for Medical Services.—A man named Wolfe has introduced a bill in the Washington legislature which seeks to regulate physicians' charges. The bill allows one dollar for each visit, and fifty cents a mile when the patient lives at a distance, and for a confinement ten dollars may be demanded, but the bill omits a guarantee of payment. Senator Wolfe seems to be out of place among lawmakers, where a modicum of common sense is desirable if not necessary.

A Change of Name.—It is proposed to change the name of the Norristown (Pa.) Hospital and Dispensary to the Charity Hospital of Montgomery County. It is alleged that under the present name the institution is frequently confounded with the Norristown Hospital for the Insane, and the other townships and boroughs in the county object to the name as being too local.

Ten-minute Headache Cures.—A protest has been made in Philadelphia against the sale of antipyrine, either openly or disguised as certain headache cure, by the druggists of that city. Many cases are cited in which very alarming symptoms have followed the taking of this "cure," one very nearly resulting in fatal collapse.

Missouri Valley Medical Society.—This society was organized in St. Joseph, Mo., and held its first meeting in that city in March, 20th to 22d. The election of officers resulted in the choice of Dr. J. M. Emert, of Atlantic, Ia., president, and Dr. J. C. Carter, of Grand Island, Neb., secretary.

A Hospital for Roxborough.—Mr. J. Vaughn Merrick, has recently given $10,000 for the establishment of a small hospital in Roxborough, Philadelphia, Pa. The hospital is to be connected with St. Timothy's Episcopal Church, and will be managed by the deaconesses attached to the parish.

In Honor of the Benzol Molecule.—A Chemical Jubilee will be celebrated in Berlin on April 11th, when the twenty-fifth anniversary of the discovery of "the structure of the benzol molecule" by Professor Kekulé, of Bonn, will be celebrated with appropriate pomp and circumstance.

To Prevent Tuberculosis.—It is proposed to appoint veterinary inspectors in Pittsburg, who shall be empowered to condemn all tuberculous meat, a reasonable compensation being paid to the owners of animals found in that condition; and who shall visit all milk dairies and condemn every cow found suffering from tuberculosis, particularly those with mammitis. It is also proposed to make it illegal to breed from tuberculous animals.

The Moses Taylor Hospital.—Mrs. George C. Lewis, daughter of the late Moses Taylor, has given an additional $30,000 for the endowment of the Moses Taylor Hospital in Scranton, Pa. The endowment now consists of $500,000, including $100,000 given by Mrs. Percy Pyne, another daughter of M. Taylor, and $50,000 by George C. Taylor. Work was commenced on this building about four years ago, but for various reasons it has been delayed, but it is probable now that it will be opened early in the summer.

Illegal Practice of Dentistry.—There are said to be nearly two hundred dentists in Philadelphia who have failed to comply with the registration law. All persons practising dentistry in the State are required to be graduates of some approved college or else to pass an examination before the State Dental Examining Board. The dentists are furthermore required to register their diplomas or certificates in the office of the Recorder of Deeds. The county dental society proposes to present the names of all delinquents to the grand jury, and two have already been indicted upon information furnished by the society.

A County Physician Wanted.—A coroner's jury at West Brighton, S. I., have recommended the appointment of a county physician, in consequence of the death of a poor woman without medical attendance.

A Portrait of Dr. Bigelow.—The artist Vinton has recently completed a portrait of Dr. Henry J. Bigelow, which is to be placed on the walls of the Boston Medical Library.

The Law concerning Hypnotism in Sweden.—The question whether a hypnotized person who acts at the suggestion of others is responsible for his actions is considered in Sweden to depend upon the fact whether he knew of the danger to which he exposed himself in being hypnotized, and submitted to it voluntarily. If so, by the law of that country, he is held responsible, otherwise not.

Recent Graduates.—Commencement exercises have been held recently in the University of Buffalo; Western Pennsylvania Medical College, Pittsburg; Rush Medical College, and College of Physicians and Surgeons, Chicago, Ill.

Blaming the Ship's Surgeon.—An action has been brought against the Allan Royal Mail Steamship Company for $10,000, by a passenger who fell down an open hatchway and broke his leg. His complaint is directed more particularly against the surgeon of the ship, whom he charges with not having paid proper attention to his injuries.

The Influenza has reached Persia, and most of the inhabitants of Teheran, including many of the Shah's household, are suffering from it.

The Douglas County (Neb.) Medical Society was recently reorganized in Omaha. The former county society went to pieces, it is said, in consequence of too much politics and personal ill-feeling between the members. It is hoped that more charity will prevail in the present organization.

A Thank-offering.—Lady Howard de Walden has expressed her intention of endowing, at a cost of £10,000 or £12,000, a ward at the West Kent Hospital, at Maidstone, as a thank-offering for her recent recovery from a serious illness.

Death of Dr. John P. Davidson.—Dr. John Pentard Davidson, one of the oldest practising physicians in New Orleans, died there on March 30th, of pneumonia, following an attack of influenza. He was a native of Mississippi, eighty-two years of age, and had practised medicine for fifty-eight years. He graduated at the University of Pennsylvania in 1832. He was one of the organizers of the Louisiana Medical Society, and was a member of the Board of Health at the time of his death. He was also Chairman of the Board of Yellow Fever Experts.

A Companion to the Crow-Bar Case, in which a crowbar was sent through the frontal lobes of the brain, is reported from Zurich. An artisan went home drunk, and fell out of a window about one hundred feet from the ground, probably in the attempt to shut it. He suffered a splinter fracture of both the frontal bones, with severe contusion of the brain in that region and efflux of brain substance. The man, who before his accident had been well-behaved, peaceable, good-natured, cheerful, and cleanly, became malicious, slanderous, quarrelsome, violent, and dirty, while no other morbid symptoms were observed.

The Convention for the Revision of the United States Pharmacopœia will be held in the city of Washington, May 7th, at noon. As it is necessary that some preliminary arrangements should be prepared in advance of the convention, Dr. Amory, President for the convention of 1880, has appointed the following delegates to act as a Committee of Arrangements: Dr. Samuel C. Busey, Dr. C. H. A. Kleinschmidt, Dr. Robert T. Edes, of Washington; Mr. P. W. Bedford, of New York, and a committee appointed by the National College of Pharmacy of the following members: W. S. Thompson, J. A. Milburn, and S. A. Waggaman, M.D. As soon as arrangements are completed a circular will be mailed to each organization whose credentials are received before April 10th, and to any delegate who will forward his address on a stamped envelope inclosed to Dr. Robert Amory, P. O. Box 3,281, Boston, Mass. The railroads in the territories of the Trunk Line Commission, Central Traffic Association, and the Southern Passenger Association, which practically includes all the lines between New York State on the East, Chicago, St. Louis, and the Mississippi River on the West, and all the Southern States, will make the convention rate of a full fare going and one-third fare returning (on the usual conditions) to all delegates and their friends to Washington and return. In the New England States and Michigan, as also north of Chicago and west of the Mississippi River no concession can be obtained.

Society Reports.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, January 22, 1890.

J. West Roosevelt, M.D., President, in the Chair.

Dr. George C. Freeborn showed three large cystic tumors which had been hardened in the fixing fluid described at a meeting in December. He presented them to show that the fluid was useful in preserving large cysts as well as small ones. The walls of the tumors were firm and resilient, looking almost as if they were tanned.

Enormous Dilatation of the Heart.—Dr. Eugene Hodenpyl presented a heart removed from the body of a man about twenty-one years of age. He was found on the street suffering from the most intense dyspnœa, and was carried as quickly as possible to the hospital. There it was found that the area of cardiac dulness was greatly increased, and it was supposed that the case was one of pericarditis with effusion. The man's condition was such that it was impossible to get a satisfactory history of the events preceding his admission to the hospital. There was extreme cyanosis and the dyspnœa was most painful. It was determined to tap the pericardium, but before this could be done the man died. At the autopsy the heart was seen to be greatly dilated, measuring seventeen inches in its greatest circumference, and nine inches in its longest diameter. When cleared of all clots it weighed about forty ounces. One cusp of the aortic valve was nearly destroyed, but the mitral appeared to be normal. The pericardium was adherent. Dr. Hodenpyl said that the question had arisen in his mind whether it would not have been justifiable to aspirate the heart, even if the true condition had been known. The patient was suffering greatly from dyspnœa, and the operation might have given him a little relief before he died.

Dr. H. P. Loomis asked whether the heart had ever been aspirated in such cases.

Dr. Hodenpyl replied that it had been accidentally aspirated several times, the diagnosis having been made of pericarditis with effusion, and the same would have occurred had an operation been attempted in this case.

Dr. Dowd asked whether the movements of the heart would not at once warn the operator that the needle had entered the ventricle.

Dr. Hodenpyl said that in a heart like this he did not think that there would be much motion, and the fact that the needle had passed into the ventricle would become manifest only by the passage through it of blood.

Dr. Northrup asked what the condition of the other organs was, whether there was any degenerative change in the kidneys, for example.

Dr. Hodenpyl answered that there was venous congestion of all the organs, but no actual disease.

Dr. Ely said that the heart was, in his opinion, hypertrophied as well as dilated—that is to say, that the actual increase in the muscular tissue was very great, owing to the enormous dilatation, although proportionately to the size of the cavities the walls were not thickened.

The President said that the heart had been aspirated a number of times. He had seen the left ventricle pierced and quite a quantity of ammonia thrown in, in a moribund person, without any apparent harm being done.

Angioma of the Larynx.—Dr. H. P. Loomis presented a specimen showing angioma involving one side of the neck, face, and tongue, and the larynx. The patient was a woman, sixty-two years of age, who first came under observation last March, suffering from chronic rheumatism. At this time there was observed a tumor, as large as an English walnut, projecting from the side of the tongue. Another mass involved the left side of the pharynx, and both tumors were continuous with a third one extending from the inferior maxillary bone to the clavicle. The tumors were of a purple color, soft, and the tumors of the pharynx and tongue could be enormously increased in size by compressing the tumor in the neck. The woman said that these tumors had existed from birth. She came under observation a second time last November. She was then in a critical condition. The tumors of the tongue and pharynx had increased to the size of a lemon; there was an enormous cervical tumor extending from the level of the orbit to the clavicle. Abdominal ascites and œdema of the legs were marked. The abdominal lymphatics, especially in the inguinal region, were enlarged to the size of the little finger. The face was cyanotic, and the dyspnœa was so intense that the patient could not lie down. The voice was not changed, but the speech was thick. There was hypertrophy of the heart, and a loud mitral regurgitant murmur was heard. The woman died four weeks after admission to the hospital. Six hours before death she passed about sixteen ounces of blood from the bowel.

At the autopsy the lungs were found œdematous and congested, and there was hypertrophy with dilatation of the heart. There was a moderate amount of chronic diffuse nephritis, and the large intestine showed submucous capillary hemorrhages. In addition to the tumors of the neck, tongue, and pharynx, there were two angiomatous growths of the larynx, one the size of a large pea projecting from the ventricle of the larynx on the left side, and the other the size of a cherry at the lowest part of the aryteno-epiglottidean fold.

Autopsy on a Case of Hydrophobia.—Dr. Loomis also presented a microscope-slide showing a section of the spinal cord removed from a boy who had died of hydrophobia, and made the following remarks: "On December 19th, Deputy Coroner Donlin requested me to make a post-mortem examination on a lad, fifteen years of age, who had been bitten six weeks ago on the wrist by a dog supposed to be mad. The boy had remained well until within four days of his death, at which time he became delirious and very violent. As his condition grew steadily worse, he was admitted to the insane pavilion of Bellevue Hospital. On the evening of December 18th he was wildly delirious, throwing himself about in his bed and on the floor. In his ravings he appeared to be afraid that somebody was going to injure him. At times he seemed for a moment to be rational. His eyes had a wild look and the conjunctiva was congested. His face was ordinarily pale, but became suddenly flushed at times. Drs. Fitch and Douglas, the physicians in charge, knowing nothing of the previous history, made a diagnosis of acute mania. The patient was vomiting profusely, and a stomach-tube was introduced and the stomach syphoned. Fifteen minutes afterward, while sitting in a chair, he suddenly died, showing some of the symptoms of asphyxia. No fluids had been given to the patient, so none of the effects of swallowing had been noted.

"The autopsy was made twelve hours after death, and with the exception of engorgement of the cerebral vessels and slight pulmonary congestion and œdema, no pathological condition could be found in any organ or tissue of the body. A microscopical examination of a section of the lower portion of the medulla showed congestion of the capillary vessels, but no structural changes. A portion of the spinal cord was removed, and was reduced by Pasteur's method to an emulsion in a porcelain crucible, and injected into the subdural space of a healthy rabbit. The animal remained perfectly well for twenty-one days, and then developed the characteristic paralysis of hydrophobia, commencing in the posterior extremities and rapidly progressing, until death occurred from paralysis of the muscles of respiration. A second inoculated rabbit died in the same manner after remaining perfectly well for twenty-three days. The classical course of the disease in the rabbits proved conclusively that they died from the virus of hydrophobia."

Photo-micrographs.—Dr. J. H. Linsley exhibited a number of excellent photo-micrographs made by Dr. W. M. Gray, of Washington. They were taken with dry

plates, and the stain used, in some of the specimens at least, was borax-carmine.

The President remarked that there was a good deal of difference in the carmine and eosine stains as regards their distinctness in photographs. In some of them there was so much blue that they were almost worthless for photographic purposes, while some others gave a stain that came out very clearly.

Dr. Freeborn said that there was considerable work of this kind done in the pathological laboratory of the College of Physicians and Surgeons, and during the last six months a black stain had been used which gave very satisfactory results. It was a dye which came from Russia, and was called "Platner's Kernschwartz," but its exact composition was not known. It stained the nuclei a deep black, while the cell-membrane and protoplasm appeared in varying shades of gray.

Preparing Hearts for the Museum.—Dr. John S. Ely showed a number of hearts to illustrate a method that he had found very useful in preparing museum specimens of these organs. The principal point was to hang the heart by the apex. The heart is first washed thoroughly in cold running water for from twelve to twenty-four hours, and if it has been cut open the parts are sewed together by discontinuous sutures. The ventricles are then prevented from collapsing by introducing a little horse-hair (a very small quantity will suffice), a thread is passed through the apex, and the heart is suspended in strong alcohol. The specimen sets more rapidly and keeps its shape better if strong alcohol be used. The auricles require no attention, for they will keep open of themselves if the heart is suspended with the apex up.

Late Hereditary Syphilis.—Dr. J. Lewis Smith presented several specimens removed from the body of a child, with the following history: About three months ago the speaker had been called to see a boy, ten years of age, in a family that he had never attended before. The first thing that he noticed on beginning his examination was that the abdomen was very greatly distended, and on palpation two distinct tumors could be made out. The first one was in the neighborhood of the spleen, and the other evidently proceeded from the liver and filled the entire upper third of the abdominal cavity. There was also considerable fluid, supposed to be serous and to result from obstruction in the portal system. There was no fever. The mother stated that the child's health had been good until within seven or eight months of the time that Dr. Smith first saw him, when his appetite began to fail, he became emaciated, and the abdomen began to increase in size. The boy was able to walk about for two months after coming under observation, but grew worse gradually, and for three weeks before death was unable to leave his bed. Toward the last there was considerable dyspnœa. The distention of the abdomen was extreme, its circumference at the time of the child's death being fully equal to that of the body of a well-developed man. It was believed that the trouble was cancer, but this was found at autopsy not to be the case, the lesions seeming to be those of syphilis. There had been no microscopical examination made as yet, but this would be done and the results would be reported to the Society at its next meeting.[1]

The kidneys were somewhat enlarged and showed the lesions of waxy degeneration, and the spleen was also waxy. It was a matter of wonder, after seeing the condition of the lungs, how the child had been able to live as long as he did, for it did not seem as though there were any chance of the blood becoming sufficiently aerated to perform its functions. The left lung was completely collapsed, and the right, though perhaps three times the size of the left, contained air only in its upper portion. The liver was also enlarged, and on gross examination was evidently syphilitic. There was no history of syphilis in the family, and the other children were healthy. One child had died, but it could not be clearly ascertained from what. The boy had exhibited no signs of hereditary syphilis in his early life, the only suspicious point that could be elicited on the closest questioning being that he had been rather subject to colds in the head, and this may have been a syphilitic coryza. The teeth and nose presented none of the appearances which have been described as characteristic of hereditary syphilis, and the patient had been perfectly well up to within two years of his death. If, on further examination, the lesions should be shown to be syphilitic, the case must be regarded as one of late hereditary syphilis.

[1] The Committee on Microscopy subsequently reported that the lesions in the liver were multiple gummata.

Mutual Transposition of the Aorta and Pulmonary Artery.—Dr. William P. Northrup presented a heart exhibiting mutual transposition of the aorta and pulmonary artery, and patent foramen ovale and ductus arteriosus. The specimen was removed from the body of a male child born in the New York Foundling Asylum. It was at first thought to be a well-formed baby, but it was early noticed to be somewhat blue, and to become markedly cyanotic on crying. It nursed poorly, and after three days became "pale-slate colored," with cold extremities. There was a loud systolic murmur, and the heart's action was violent and palpitating, though the pulse was regular, of fair quality, and 160 to 180 in the minute. Respiration was normal. The child was dull, but easily aroused, and would then become very cyanotic. There were some small abrasions about the nose which never healed, but remained as dark red spots. After a week the child ceased to nurse altogether, and developed bronchitis. There was no œdema. The cyanosis was most marked in the upper extremities. (For this history Dr. Northrup was indebted to the house-physician, Dr. George S. Lynde.)

Autopsy.—The brain was not examined. The skin was of a bluish dirty-white color. The liver was intensely congested; the kidneys were congested, firm, and dark-red in color; the spleen was small and shrivelled; the thymus was large, and the stomach and intestines were normal. There was a mutual transposition of the aorta and pulmonary artery. When *in situ* the origins of these two great vessels were plainly visible, the aorta arising from the conus arteriosus of the right ventricle, the pulmonary artery from the usual point of origin of the aorta in the left ventricle. The correlation of parts is best understood if we consider this supposition: The aorta and pulmonary artery are separated from their usual attachments, the hypertrophied heart rotated on its longitudinal axis from left to right, the aorta attached to the apex of the conus arteriosus, and the pulmonary artery attached to the point of usual origin of the aorta. It is easily understood that the right ventricle was rolled downward, the auricle nearly disappearing beneath the aorta in its new location, while the left ventricle made its appearance and presented as much surface to view as did the right ventricle, and also showed much of the corresponding (left) auricle. A drawing was exhibited showing schematically the relative shape and correlation of parts. It showed the two auricles and ventricles in equal degree. The left coronary artery, which is usually seen near the subject left cardiac margin, was shown passing down over the middle of the anterior surface of the heart. It was given off from the aorta and passed downward over the septum ventriculorum. The heart was large for the age of the child, and was hypertrophied in all its walls, most notably in those of the left auricle and ventricle. The ductus arteriosus was patent. The aorta, before receiving the abnormally large ductus, suffered marked constriction. At the point of juncture of the proximal wall of the ductus with the wall of the aorta there was a concentric fold, made up of aortic wall and ductus, which served to direct the blood-stream upward into the vessels of the neck. The foramen ovale was open at its anterior margin, the aperture being about as large as the aorta at its point of constriction. The membrane closing most of the original foramen was thick and redundant, forming a valve sufficient to close the foramen under pressure from the right auricle, but calculated to open under pressure from the

left. In case the blood-pressure in the left auricle exceeded that in the right, there would be a current from left to right, but in no case from right to left. Otherwise the auricular septum was complete. The ventricular septum was complete. In short, there were no anatomical changes not directly dependent upon the interchange of points of origin of the aorta and pulmonary artery. The venæ cavæ emptied into the right auricle, the pulmonary veins into the left auricle.

The Course of the Circulation.—Venous blood entered the right auricle and ventricle through the venæ cavæ, and passed through the transposed aorta to the vessels of the neck and arms. Aerated blood from the lungs passed through the left auricle and ventricle to the pulmonary artery, much of it passing through the ductus arteriosus to the descending aorta on the distal side of the constriction. There was a commingling of blood-streams at this point. Again there was, no doubt, commingling of streams by blood passing from the left to the right auricle through the valve-like redundant membrane of the foramen ovale. In other words, there were two circuits—an arterial and a venous—which commingled at two points, the stricture of the aorta and the foramen ovale. The coronary arteries were given off from their usual locations at the beginning of the aorta, and received their arterial blood from the current which came through the foramen ovale. The lower extremities must have received a good supply of arterial blood direct from the pulmonary veins, left auricle and ventricle, pulmonary artery, and ductus arteriosus. These facts explain the marked cyanosis of the face and hands, and the palpitation of the heart.

The Society then went into executive session.

Stated Meeting, February 12, 1890.

J. West Roosevelt, M.D., President, in the Chair.

Dr. John S. Ely reported that, at the request of Dr. J. Lewis Smith, a microscopical examination had been made of the liver presented at the last meeting of the Society. The lesion was found to be multiple gummata.

Acute General Miliary Tuberculosis.—Dr. J. H. Linsley presented specimens and slides from a case of acute general miliary tuberculosis occurring in a child of twenty-two months. The child had been bottle-fed on condensed milk up to about three months ago, since which time soups, oatmeal, and cow's milk had been added to the diet. He had never been sick up to three months ago, at which time he was attacked with vomiting of such severity that almost all the food was rejected by the stomach. This vomiting continued pretty constantly for three or four weeks, the abdomen meanwhile increasing gradually in size, and the child emaciating perceptibly. Two weeks before admission to the Hospital of the Post-Graduate School he began to cough at night, and had some fever. On admission, January 7th, the child was seen to eat fairly well, but did not seem to be nourished by his food. The child lived in Brazil from the age of eight weeks to that of eight months, and the mother thought that there was some malarial complication. He had a peculiar nodding and tremulous motion of the head, and also what seemed to be a facial paralysis on the left side. The treatment consisted in the administration of cod-liver oil, hypophosphites, and iodide of iron, and the diet was composed of bread and milk and soup; but the child nevertheless failed steadily, and died on January 25th.

Autopsy.—The peritoneum was normal, but the mesentery was the seat of numerous small miliary tubercles, and the mesenteric glands were enlarged and indurated. The liver extended below the free border of the ribs a distance of five centimetres. Upon removing the calvaria a large amount of clear fluid escaped from the cranial cavity. The amount could not be estimated with any degree of accuracy, but it was several ounces. The dura mater was firmly adherent to the calvaria, and the vessels of the pia were deeply congested; the pia itself was thickened, and over the portion of the brain corresponding to the occipital lobe there was a considerable exudation of lymph beneath the pia, having an opaque appearance. The substance of the brain was very soft, and all the vessels leading to it were deeply congested. Upon removing the brain and resting it on its inferior surface, the two hemispheres flattened out and separated, exposing the whole ventricular area. The corpus callosum was almost entirely destroyed, and the lateral ventricles were enormously distended with fluid, their cavities reaching to within two centimetres of the exterior surface of the cortex posteriorly. There was an extensive tuberculous deposit on the exterior surface of the anterior portion of the middle lobe of the cerebellum, immediately beneath the roof of the fourth ventricle, and immediately posterior to this was a large suppurating cyst. The pressure upon the veins of Galen must have been considerable, and would account for most, if not all, of the fluid in the ventricles. The heart was normal. There were firm pleural adhesions all over the right side, but none on the left. The left lung was well aerated, and was studded with miliary tubercles throughout its substance, a few being seen on the surface. The right lung was somewhat collapsed, very poorly aerated, and miliary tubercles were to be seen on its surface. On section the cut surfaces were seen to be studded with small miliary tubercles. The bronchial glands were enlarged, of a firm cheesy consistency, and of a whitish appearance. The left kidney was normal in size and slightly lobulated. In the upper portion of the organ were felt numerous hard nodules, and in the lower portion, for a distance of three centimetres, was a hard, whitish, cheesy mass occupying the entire thickness of the organ. The capsule was not adherent except over the portion corresponding to this cheesy mass. The surface was mottled reddish and white, and there were a few miliary tubercles in the cortex. On section the markings were fairly distinct, and about the centre of the organ there was a small whitish nodule half a centimetre in diameter. In the right kidney the capsule was not adherent. A small discolored area, having the appearance of an infarction, was seen on the lower and anterior surface. Upon section the pelvis was seen to be enormously dilated, the markings were obliterated, and numerous miliary tubercles were seen in the cortex. The left ureter was normal in appearance, but the right was greatly dilated and there was a hard whitish mass, about four centimetres from the kidney, which entirely filled the lumen of the tube. The spleen was greatly enlarged and contained two cheesy masses.

Examination for bacilli was negative for the lungs, but the micro-organisms were found in sections of the kidneys, liver, and spleen.

The case was not an unusual one, but was presented mainly for the reason that it was in the line of a number of cases of tuberculosis which had been presented to the Society this winter, in which the lesion in the lung was the least marked. The most extensive deposit was found in the kidney, and it was here also that bacilli were found in greatest abundance.

Dr. Northrup thought that cheesy masses, as distinguished from miliary tubercles, were very rare in the kidneys, and said that the demonstration of bacilli was especially difficult in them.

Dr. Linsley, in answer to questions, said that he did not know the original point of entrance of the bacilli. The bronchial glands were not broken down. The renal lesion was the most marked of any.

Dr. Fisher said that in an older subject we would expect to find some interference with co-ordination in a lesion of the middle lobe of the cerebellum.

Aneurism of the Arch of the Aorta.—Dr. R. G. Freeman presented a specimen, for which he was indebted to Dr. J. S. Thacher, of aneurism of the arch of the aorta. The patient was admitted to St. Luke's Hospital complaining of moderate pain in various parts of the chest, and inability to swallow solid food, although there

was no pain on swallowing. He could take fluid nourishment. These symptoms had been present for two months. On admission the pulse was one hundred and regular. The radial arterial wall was a little thickened. Over the whole chest a few moist râles were heard, and over the left chest was feeble breathing. The urine was normal. There was flatness on percussion over the upper third of the sternum, but no pulsation or murmur. A systolic murmur was heard over the apex of the heart. There was paralysis of the left vocal cord. At the autopsy an aneurism was found involving the ascending and transverse portion of the arch of the aorta, four and a half inches in diameter. It contained no laminated fibrin, but a moderately firm and slightly adherent white clot. The œsophagus was ulcerated from the level of the bifurcation of the trachea to a point two inches above. Posteriorly the ulcer had perforated into the connective tissue, producing suppuration with a gangrenous odor. In front of the œsophagus a cavity had been formed in the connective tissue, an inch an a half in diameter, extending down to the diaphragm. The heart was normal. The specimen showed a large fusiform dilatation of the aorta, beginning just above the valve, increasing gradually in size, and ending in a sacculation of the summit of the aorta. All the large vessels of the neck were given off from the aneurism. The points of special interest were the absence of pulsation and murmur over the aneurism, although it was of considerable size, and also the paralysis of the left vocal cord due to pressure on the left recurrent laryngeal nerve. Microscopic examination of the heart muscle showed it to be normal. Sections of the aorta and aneurismal wall showed only the usual changes.

Dr. Messenger recalled a case of a similar, but much larger, aneurism, which on autopsy was found adherent to the spine and both chest-walls, laterally and anteriorly. There had been a most distressing cough for several years. The patient died from interference with the respiration.

The President remarked that such aneurisms need not necessarily pulsate, and that this specimen showed no fibrous bands or rough walls, a fact which might explain the absence of the murmur. He did not see why there should have been a systolic murmur at the apex.

A Fleshy Mole.—Dr. Charles N. Dowd presented a fleshy mole which was passed by a dispensary patient about two days after the uterus had been curetted. These moles are usually formed from fœtal membranes which remain in the uterus after abortion or the death of a young fœtus, extravasated blood aiding in their formation; or the retained placenta of an older fœtus may form an entire mole. The so-called false moles may be produced from a submucous fibroid which becomes detached from its pedicle, from the mass expelled in membranous dysmenorrhœa, or from a simple blood-clot. The patient who passed this mole gave the following history: She was thirty-six years of age, in fair general condition, denied ever having had syphilis. She had had five children, the last one three years ago, and two miscarriages previous to the last child. She menstruated last on April 1st, and on August 1st had the ordinary signs of pregnancy. At this time she began to pass clots, and although she looked for the fœtus, found none. The hemorrhages continued with more or less severity for four months, during the last two of which she was under observation at the dispensary. The mole was passed only after the uterus had been curetted, and thus the mole, which was the placenta of a four months' fœtus, had been retained in the uterus for four months after abortion. On examining the specimen the following features were noted: It was an ovoid mass of firm consistency, $2\frac{3}{4} \times 1\frac{1}{4} \times \frac{3}{4}$ inches in size. At the back there were some adherent membrane and a few dense clots. The rest of the surface was fairly nodular. Microscopical examination showed placental structure in a condition of interstitial inflammation. The placental tufts showed a large amount of dense connective tissue. Vascularity was much diminished. There were numerous calcareous deposits, and the entire structure was much compressed. The specimen was compared with a section of a normal placenta which was placed beside it. This interstitial placentitis is very common,[1] and it is certainly probable that it was the cause of the abortion.

Dr. Dowd also presented some other specimens illustrating other forms of moles. The first was a fleshy mole in which the membrane and decidua were found. Ziegler[2] says that this occasionally follows disease of the decidua or decidual hemorrhage. Birch-Hirschfeld[3] says that the spaces between the chorionic villi are filled with coagulated blood, and that the chorion and amnion are sometimes bound firmly together by the clot.

False Fleshy Mole.—The second false mole was really a submucous fibro-myoma, which in general appearance resembled closely the placental mole previously presented. These tumors extend into the uterine cavity and become separated and expelled. The separation is supposed to be caused by the constriction of the pedicle or the vessels of the pedicle, which comes from the efforts of the uterus to expel the mass. Another specimen was presented, showing the fibro-myoma in the uterus attached by a firm pedicle.

A discussion followed on the manner in which atrophy of the pedicle of the fibroid moles was brought about.

Dr. M. P. Jacobi held that there was no diminution in the size of the uterus at the site of the pedicle, therefore no pressure was exerted around the pedicle.

The President, as well as the reader of the paper, took the position that there was, notwithstanding this, a stenosis of the vessels of the pedicle, caused very probably by the traction upon the mole, either from the efforts of the uterus to expel it or from its own weight.

Tuberculosis of the Lungs and Supra-renal Bodies.—Dr. H. M. Biggs presented specimens showing these lesions, removed from the body of a man who had been admitted to Bellevue Hospital suffering from influenza. He had a general bronchitis, which cleared up well with the exception of several small areas of consolidation. His general condition became very good. Suddenly he grew worse, went into collapse, and was dead within five hours. The necropsy did not explain the cause of death. In both lower and upper lobes of the lungs there were six or eight small tubercular areas, surrounded by recent broncho-pneumonia. The bronchial glands were swollen but not cheesy. There were no tubercles elsewhere except in the supra-renal capsules, which were entirely replaced by cheesy masses. There was no pigmentation of the skin. Dr. Biggs was certain that these cheesy masses were tuberculous, although he had made no microscopical examination. He had seen two other cases of tuberculosis with lesions of the supra-renal capsules, and without pigmentation. One had tuberculous nodules in the cerebellum, cerebrum, kidneys, bladder, prostate, supra-renal capsules, and spleen, with a recent lesion in the lung. The other was a case of general miliary tuberculosis. He considered the real lesion in Addison's disease an affection of the sympathetic system. The lesions of the supra-renal bodies might be tuberculous, cancerous, hemorrhagic, or occasionally atrophic.

Dr. Northrup had seen a case with dirty brown skin, whitish cheesy bodies replacing the supra-renal capsules. The lesion was found to be hemorrhagic.

Dr. M. P. Jacobi said that she had always considered the lesion in Addison's disease a true atrophy. She suggested as the cause of the sudden death a generalized tuberculous infection not old enough to have caused lesions which were demonstrable.

The President asked for examination of the pneumogastric nerves in cases such as this. There was probably no mechanical obstruction to the circulation in this case.

Supernumerary Nipple.—Dr. Mary Putnam-Jacobi presented a specimen of a supernumerary nipple which was attached by a narrow and short pedicle to the sum-

[1] Hirst: American System of Gynecology, vi., p. 243.
[2] Spec. path. Anat., vii., p. 883. [3] Path. Anat., vii., p. 802.

mit of the normal nipple. It was of the same size as the normal nipple, and of the same structure, though the ducts were slightly more dilated. It had appeared at the age of thirty years, after the birth of a child, and had grown gradually during the past fifteen years up to its present size. It had caused no inconvenience at all until the last two days, when there had been a little pain, probably from unusual pressure. Dr. Jacobi considered the case extremely rare.

Dr. Northrup had tied off a small growth from the summit of the nipple once, without thinking much about it. It may have been a similar growth.

Bicuspid Aortic Valve.—Dr. H. M. Biggs showed a bicuspid aortic valve. The valve had been perfectly competent, and the heart was not at all enlarged.

The President had seen the aortic valve with four cusps, but had never seen one like this.

The Society then went into executive session.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

A UNIQUE SERIES OF CASES OF VESICAL CALCULUS—THE PROPOSED HOSPITAL FOR THE INSANE IN LONDON—THE ARMY MEDICAL DEPARTMENT—THE POSSIBILITY OF DISPENSING WITH THE MEDICAL EXAMINATIONS OF PERSONS ASSURING THEIR LIVES.

London, March 15, 1890.

A remarkable record of operations for vesical calculus was presented to the Medical and Chirurgical Society at its last meeting by Sir Henry Thompson. He had previously (in 1878) brought before the same society a series of 500 cases, but in the past twelve years he has added 464 cases to his list, making a total of 964—a record probably unapproached by any living British surgeon; of this number 101 were hospital, and the remainder (863) private cases. Of the total number of cases only 17 were those of children and only 14 those of women. Full notes had been made of every case at the time and almost every calculus had been preserved; the calculi were shown. An analysis of the entire series of cases showed that stone in the bladder was not more common in children than in adult patients, as was formerly supposed from the experience of hospital practice. The mean age of the entire adult male cases was about 62 years. Taking the male private patients alone, only 100 (out of 849) were under 50 years of age. The greatest age at which an operation (lithotrity) had been performed was 91 years. The largest calculus weighed 14 ounces and was composed of uric acid. Sir Henry Thompson urged the value of the principle, long ago insisted upon by him, of finding the calculus at the earliest date possible, for the adult elderly male, in whom it so frequently occurred. Two cogent reasons existed for this: 1, the stone when small was easily removed and with little risk; 2, at that stage of calculus production the re-formation of an acid calculus (uric or oxalic) could almost invariably be prevented by strict dietetic precautions. In the entire adult series of 933 cases, 800 were by lithotrity, 115 by perineal lithotomy, and 18 by suprapubic lithotomy. The author's earliest case of lithotrity was in 1854. He had commenced at that time with the method of Civiale. In 1865, Clover introduced the aspirator for removing *débris*. In 1878, Professor Bigelow introduced the great and important principle of employing only one sitting and removing the whole of the *débris* at once. Sir Henry Thompson had at once adopted this method, and, as a result, the mortality of his cases was reduced nearly one half, as shown by comparing his own 325 cases of the operation by a single sitting with the 475 by multiple sittings prior to the date named.

Mr. Bryant remarked on the enormous advance made by the introduction of the operation of lithotrity at one sitting by Bigelow, which he considered the most important since the question of operation for stone had been dealt with at all by surgeons. Referring to lithotomy, he said it was evident that the lateral was gradually being put aside for the suprapubic method. Under what circumstances would Sir Henry Thompson prefer the suprapubic method to lithotrity in adults, and under what circumstances would he adopt the suprapubic operation in preference to the perineal one in children? All would agree as to the importance of dealing with a stone at the earliest possible stage, and both physicians and surgeons were now in the habit of examining the bladder at once if there were signs of persistent irritation.

Mr. Buckston Browne observed that he scarcely knew how to classify certain of his cases. Sir Henry Thompson had laid it down that removal of phosphatic concretions was not to be considered as an operation of lithotrity, and he had also fixed an arbitrary limit of twenty grains, to concretions below which weight the name stone was not to be applied. On the other hand, Surgeon-Major Freyer, in recording his Indian experiences, had grouped together stones weighing three and four grains, and stones weighing an ounce or more. Mr. Buckston Browne exhibited three hundred calculi, their combined weight being only one hundred and seventy grains, which he had himself removed from a patient's bladder through a tube, no lithotrite being used. He thought the time had come when three designations should be used for cutting, crushing, and washing out; "lithotomy" and "lithotrity" for the two former, while the term "lithoplaxy" should be reserved to imply the removal of a stone or stones without the use of the knife or lithotrite.

The President (Mr. Timothy Holmes) said one of the most important points raised was the possibility of detecting and removing a stone early, and another equally important and gratifying point was the possibility of guaranteeing the patient from the risk of recurrence if he would adhere to a properly regulated diet. The re-introduction of suprapubic lithotomy made it possible to remove a mass of enlarged prostate if that condition occurred as a complication of stone. It was satisfactory to notice that in a large proportion of cases after lithotrity the cure seemed to be definite. He asked whether the children of the poor met with in hospitals were better dealt with by lithotomy or lithotrity? He had himself had such ample reason in these cases to be satisfied with the former that he had never tried the latter, but he believed that the results of lithotrity in children had been exceedingly favorable in India.

Sir Henry Thompson then replied. He said: The question whether lithotomy or suprapubic lithotomy was the better operation in the adult and in the young patient respectively, was an exceedingly difficult one for him to answer, believing as he did so strongly in the importance of the "personal equation" in the operator. He found, indeed, the question even more difficult to answer now than formerly. In the case of children, he had employed lithotrity for stones of moderate size, but very large ones, which some perhaps might crush, he would prefer to cut. He liked the suprapubic operation for boys, for the wound could be closed at once, but in adults he preferred a free opening, allowing drainage for some days afterward. In the adult, crushing might be carried to stones of four ounces if one chose, provided a large evacuating-tube could be passed. In connection with this, he observed that the adult male of sixty-five to seventy-five, possessed as a urethra a very insensitive and capacious channel, while the most irritable urethra he had found in men of from twenty-five to forty, and any over-distention of these frequently gave rise to trouble. If an evacuating-tube as large as No. 18 could be passed, a three-ounce uric-acid stone when crushed could be removed with great facility. If he found an irritable passage with a rigid prostate, admitting only a No. 13 or 14, he preferred to employ the suprapubic operation for a large calculus. His experience with children was but small, but in them lithotomy had given good results. The difficulty of completely

evacuating a bladder had been practically abolished since the introduction of the modern powerful aspirators, but there would still be a re-formation of deposit in cases of enlarged prostate; this was only to be prevented by frequently washing out the bladder.

The proposal for a hospital in London for the curative treatment of insanity has been shelved for the present, as the London County Council has postponed the further consideration of the subject for six months. The question of expense has doubtless done much in guiding them to this decision.

The attitude of the Secretary of State for War, in refusing to carry out many of the recommendations of Lord Camperdown's committee, is provoking much adverse comment. Mr. Stanhope's refusal to publish the evidence laid before the committee is also keenly criticised. When the supply of army surgeons falls off, probably the government will do something, but at present the candidates are always more numerous than the vacancies.

The question is being discussed of the possibility of dispensing with the medical examinations of persons assuring their lives. It has been suggested that, under certain conditions, such examinations may be dispensed with without placing undue risks on the insurance offices.

THE MANAGEMENT OF HIP-JOINT DISEASE FROM AN ANATOMICO-PATHOLOGICAL BASIS.

To the Editor of the Medical Record.

Sir: My attention was called recently, for the first time, to an error, probably made by the printer, in a paper published in the Record, May 4, 1889, by the above title.

In that paper I am made to say (see page 478, just underneath Fig. 2), "No apparatus has heretofore been devised which will so perfectly fix a hip-joint as double extension in bed—the body and well leg fixed to a long splint—first recommended, I believe, by Dr. Sayre (see Fig. 3)."

A *dash* has been substituted for the *period* after *bed*, and the next sentence commenced with a small letter. The word *are* is also dropped between the words *leg* and *fixed*, which changes the meaning intended. The sentence should read, "No apparatus has heretofore been devised which will so perfectly fix a hip-joint as double extension in bed. The body and well leg are fixed to a long splint, first recommended, I believe, by Dr. Sayre, See Fig. 3."—Portable should read portative, page 477, fifth line from top.

Truly yours,

A. M. Phelps, M.D.

144 West Thirty-Fourth Street, March 25, 1890.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 23 to March 29, 1890.

Jarvis, N. S., First Lieutenant and Assistant Surgeon. Leave of absence granted for one month, with permission to apply for an extension of fifteen days. Par. 1, S. O. 34, Headquarters Department of the Missouri. Fort Leavenworth, Kan., March 20, 1890.

Taylor, Marcus E., Captain and Assistant Surgeon. By direction of the Secretary of War authority is granted for his admission to the Army and Navy General Hospital, Hot Springs, Ark., for treatment therein. Par. 6, S. O., A. G. O., March 21, 1890.

Taylor, M. E., Captain and Assistant Surgeon. Leave of absence granted for one month, based on surgeon's certificate of disability, with permission to apply for an extension of one month. Par. 3, S. O. 26, Headquarters Department of the Columbia, March 18, 1890.

Birmingham, Henry P., Captain and Assistant Surgeon. By direction of the Secretary of War is relieved from station at Fort Klamath, Ore., and from temporary duty at Vancouver Barracks, Washington, and will report in person to the commanding officer, Boice Barracks, Ida., for duty at that post. Par. 6, S. O. 72, A. G. O., Washington, D. C., March 27, 1890.

Official List of Changes in the Medical Corps of the United States Navy for the week ending March 29, 1890.

Ames, H. E., Passed Assistant Surgeon. Ordered to Museum of Hygiene, Washington, D.C.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 29, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	8	2
Scarlet fever	79	9
Cerebro-spinal meningitis	4	1
Measles	224	14
Diphtheria	101	24
Small-pox	0	0
Varicella	2	0
Cholera	0	0

A Double Monster.—There is now on exhibition in England a double monster, known as the Tocci Brothers. The children are thirteen years of age, and were born of an Italian woman living in humble circumstances. The body as far as the shoulders is single, but is double above. The stomach is common to the two children, and if one eats heartily the other has no desire for food, yet it is said that the two are very unlike in their appetites and tastes, one being fond of sweets while the other cares only for substantials. The genital organs are male, but the face of one of the children is very feminine in its appearance.

Circular of Information for Medical Men who may be desirous of entering the United States Army Medical Department.—The Medical Department of the Army consists of one surgeon-general with the rank of brigadier general; one assistant surgeon general, one chief medical purveyor, and four surgeons with the rank of colonel; two assistant medical purveyors and eight surgeons with the rank of lieutenant-colonel; fifty surgeons with the rank of major; and one hundred and twenty-five assistant surgeons with the rank of first lieutenant of cavalry for the first five years of service, and of captain of cavalry subsequently until their promotion by seniority to a majority. With the rank stated in each case the pay and emoluments of the rank are associated. The salary of each grade is a fixed annual sum payable monthly; but at the end of each period of five years of service the annual sum representing the pay of the grade is increased by ten per cent. until forty per cent. is added. After twenty years of service the forty per cent. additional continues to be drawn, but the further increase of the pay by ten per cent. additions ceases, *i.e.*, an officer, although he may have served twenty-five or thirty or more years can, under existing laws, have no more than forty per cent. added to his pay proper by way of increase for length of service. The pay of a first lieutenant of cavalry, or of a medical officer during the first five years of his service is $1,600 per year, or $133.33 per month. At the expiration of his five years of service he becomes, by virtue of that fact, a captain, and his pay is that of a captain of cavalry, $2,000 per year, increase by ten per cent. for his years of service,

viz., $2,200 annually, or $183.33 monthly. At the end of his tenth year of service this rate of pay is increased by the service-addition to $2,400 annually, or $200 per month, and after five years more the service-addition makes his pay $2,600 annually, or $216.67 per month. If he continue in the rank of captain, at the end of twenty years of service his monthly pay becomes $233.33; but about this time promotion to a majority is usually obtained, and a major's annual pay of $2,500, with forty per cent. added, makes the monthly pay of the major and surgeon $291.67. Subsequent promotion, investing the individual with the rank of lieutenant-colonel, colonel, and brigadier-general, augments the monthly pay respectively to $333.33, $375.00, and $458.33. Compulsory retirement at the age of sixty-four years increases the rapidity of promotion to the younger men; and when retirement is effected either by age or by the accidents of service prior to reaching the retiring age, the rate of pay subsequently drawn is seventy-five per cent. of the total salary and increases of the rank held by the individual at the time of his retirement. Thus, a major retired for broken health after twenty years' service draws seventy-five per cent. of $291.67 per month; a colonel retired for age, seventy-five per cent. of $375.00. The medical officer has the right of selecting quarters in accordance with his rank, and when stationed in a city where there are no Government quarters, commutation money, intended to cover the expense of house-rent, is paid to him. The Government provides forage and stable room for the horses of the medical officer, and when travelling under orders the expenses of transportation are paid by the Quartermaster's Department.

Among the privileges granted to medical, as to other officers of the army, is that of leave of absence on full pay. The authorized leave amounts to thirty days annually. This leave is not forfeited if not taken during the year, but is credited to the officer, who may thus accumulate a continuous leave of four months on full pay. If he desires to be absent for a longer period than four months, and the permission is accorded him, he is reduced to half-pay for all time in excess of the four months or maximum of cumulated leaves of absence. Absence from duty on account of sickness does not affect the relations of the officer with the paymaster; he continues to draw full pay.

A commission in the Medical Department of the army is an instrument which is good for life, premising conduct consistent with its retention on the part of its possessor; but it involves no contract which binds the individual to service for any given number of years. On the contrary, should the medical officer find on experience that civil life has greater attractions for him than that of the army, there is nothing to prevent him from at any time tendering the resignation of his commission.

A young medical officer on appointment is usually assigned to duty for a few months at some large post where there are other officers of his department, to afford him opportunity of becoming acquainted with the requirements of the Army Regulations and the routiné duties of military life. After this he goes to some post west of the Mississippi River, where he serves a tour of duty of four years. An assignment in the East follows the leave of absence which is usually taken at this time; and in after years his stations are selected so as to give him a fair share of service at what may be called desirable posts as an offset to the time spent at less desirable stations.

Candidates for appointment to the Medical Corps should apply to the Secretary of War for an invitation to appear before the Army Medical Board of Examiners. The application should be in the handwriting of the applicant, should give the date and place of his birth, and the place and State of which he is a permanent resident; it should be accompanied by certificates based on personal acquaintance from at least two persons of repute as to citizenship, character, and moral habits. Candidates must be between twenty-one and twenty-eight years of age (without any exceptions), and graduates of a regular medical college, evidence of which, the diploma, must be submitted to the Board. The morals, habits, physical and mental qualifications and general aptitude for the service of each candidate will be subjects for careful investigation by the Board, and a favorable report will not be made in any case in which there is a reasonable doubt.

The following is the general plan of the examination: I. The physical examination will be rigid; and each candidate will, in addition, be required to certify "that he labors under no mental or physical infirmity, nor disability of any kind, which can in any way interfere with the most efficient discharge of any duty which may be required." II. Oral and written examinations on subjects of preliminary education, general literature, and general science. The Board will satisfy itself by examination that each candidate possesses a thorough knowledge of the branches taught in the common schools, especially of English grammar, arithmetic, and the history and geography of the United States. Any candidate found deficient in these branches will not be examined further. The examination on general science will include chemistry and natural philosophy, and that on literature will embrace English literature, Latin, and history, ancient and modern. Candidates claiming proficiency in other branches of knowledge, such as the higher mathematics, ancient and modern languages, etc., will be examined therein, and receive due credit for their special qualifications. III. Oral and written examination on anatomy, physiology, surgery, practice of medicine, general pathology, obstetrics and diseases of women and children, medical jurisprudence and toxicology, materia medica, therapeutics, pharmacy, and practical sanitation. IV. Clinical examinations, medical and surgical, at a hospital, and the performance of surgical operations on the cadaver.

Due credit will be given for hospital training, and practical experience in surgery, practice of medicine, and obstetrics. The Board is authorized to deviate from this general plan whenever necessary, in such manner as it may deem best to secure the interests of the service.

The Board reports the merits of the candidates in the several branches of the examination, and their relative merit in the whole, according to which the approved candidates receive appointments to existing vacancies, or to vacancies which may occur within two years thereafter. At the present time there are 7 vacancies to be filled. An applicant failing in one examination may be allowed a second after one year, but not a third. No allowance is made for the expenses of persons undergoing examination, but those who are approved and receive appointments are entitled to transportation in obeying their first order assigning them to duty.

Copies of examination papers used by the Board in session in New York City in October last, are hereto appended as an illustration of the character of the questions submitted to candidates.—JOHN MOORE, Surgeon-General. Approved: REDFIELD PROCTOR, Secretary of War. War Department, Surgeon-General's Office, Washington, D. C., December 12, 1889.

SPECIMENS OF EXAMINATION PAPERS (used by the Army Medical Examining Board, in session in New York City, October, 1889).

Arithmetic.—1. Change 0.194 to an equivalent fraction whose denominator is 432. 2. How many inches are there in 0.0625 of a yard? 3. What is the percentage of mortality in pneumonia when 13 deaths occur in 64 cases? 4. A barometer indicates 29.36 inches; what is its height in millimetres? 5. 9.17 : 13.83 : : 19.34 : ? 6. What is the cube and cube root of 3.6? 7. By what principle of trigonometry is the distance of certain stars ascertained? Illustrate by diagram. 8. How do you ascertain the solid contents of a cylinder?

Geography.—1. Name eight rivers of the United States that empty into the Gulf of Mexico. 2. What large lake in the United States is at the greatest altitude? Where is it? And what is its approximate elevation? 3. Give the

boundaries of Montana, and briefly mention its general geographical features. 4. Describe the route you would take in going from St. Louis, Mo., to the City of Mexico, and name the States through which you would pass. 5. Mention two or three cities of Europe that are in nearly the same latitude as New York. 6. Name the capital of Saxony, of Bavaria, and of Switzerland. 7. What do you consider to be a small, and what a large, annual rainfall? 8. A storm is approaching, passes to the south of the observer in the Eastern U. S., and out to sea. Describe the changes of the wind that would occur.

History and Literature.—1. Give the names of the principal Roman deities, and the corresponding names used by the Greeks. 2. State what you know in regard to the date and object of the Magna Charta. 3. Who was Galen? And in what century did he live? 4. Give a brief account of Mohammed. In what century did he live? 5. Who was Frederick the Great? Mention some of his victories. 6. Give the particulars of General Arnold's treason. 7. Mention the leading events in the administration of President Madison. 8. Give the names of at least eight of Shakespeare's plays, and the approximate dates of his birth and death. 9. Mention the principal works of Victor Hugo. 10. Name the best known works of George Eliot. State what you know about this writer.

Physics.—1. What are the differences between the solar day and the sidereal day? 2. What portion of the earth's quadrant does the French metre represent? 3. Does the weight of a given mass increase or diminish as you go from the equator to one of the poles? Give the reason. 4. Describe the Torricellian vacuum. 5. Describe the process of ebullition. 6. What is Newton's first law of motion? 7. What is osmosis? What effects have heat and electricity on it? 8. Which color of the solar spectrum is produced by the slowest vibration of ether waves.

Chemistry.—1. Explain briefly the determination of atomic weight by means of specific heat. 2. What other elements belong in the same natural group with sulphur? 3. Describe briefly the chemistry of glass-making. 4. State the physical and chemical properties of aluminium. 5. Mention some of the analytical reactions of the proteids. 6. What are the principal forms in which nitrogen enters into organic compounds? 7. What ptomaines have been isolated? What other substances do they resemble in physiological action and chemical reaction? 8. Mention some tests for morphine.

Anatomy.—1. Give the origins and insertions of the triceps muscle of the arm. State its actions, and describe its relations to neighboring parts. 2. Give the origin, course, and relations to neighboring parts of the ophthalmic artery, and name its branches and the parts to which they are distributed. 3. Mention the nerves that supply the tongue, and describe the special parts supplied by each, and the kind of nervous supply in each case. 4. Describe the structure, location, attachments, and relations of the ligamentum denticulatum, and state its uses. 5. Describe the structure, course, and relations of the ureter proper. 6. Describe the relations of the trachea in the neck.

Physiology.—1. By what means is the exchange of gases between the blood of the pulmonary capillaries and the air in the air-vesicles effected, and what is the nature of the process? 2. State the differences between the gastric and pancreatic digestion. 3. Describe the various modes of origin of the lymphatics within the different issues. 4. Describe the different forms of reflex action and give an example of each. 5. State the changes that take place in the Graafian follicle, from which the ovum has been discharged.

Surgery.—1. Describe hospital gangrene, its treatment, constitutionally and locally. What preventive measures check its spread? 2. What are the constitutional manifestations of secondary and tertiary syphilis, and the appropriate treatment? 3. When is phlebotomy demanded? 4. Describe the operation of exposing the inferior dental nerve in its course in the body of the bone. 5. What are the indications for abdominal section or laparotomy? 6. What are the four primary forms of club-foot? Name the contracted muscles in each variety. 7. What pathological condition may follow ligation of veins? 8. Describe the various operations for stone in the bladder.

Practice and Pathology.—1. What are the anatomical characters of lymphadenomia? 2. Give the pathology of uræmia. 3. What are the pathological results of chronic alcoholism? 4. What course or courses of treatment would you pursue in cases of acute or chronic dysentery? 5. Give an account of the treatment of acute pneumonia. 6. What are the causes and the usual location of rupture of the heart? 7. Give the clinical history of chronic diffuse nephritis. 8. Give the symptoms of gout, and the differential diagnosis of gout and rheumatism. 9. What is the differential diagnosis of the eruptions of scarlatina, roseola, and measles? 10. Mention the principal animal parasites of man.

Obstetrics and Diseases of Women and Children.—1. What are the causes of severe vomiting in pregnancy? How can it be controlled? 2. What is puerperal eclampsia, the means of prevention, and the treatment in early pregnancy and during labor? 3. Describe the utero-placental circulation. 4. Give the signs of pregnancy. 5. What are common causes of abortion? State the preventive measures, and the treatment when it occurs. 6. Give the causes of tedious labor; mention two cases and the appropriate treatment for them. 7. What are the most dangerous diseases of children? 8. What are the earliest symptoms of tetanus nascentium? What are the supposed causes of it?

Materia Medica and Therapeutics.—1. Give the source and composition of eucalyptus; name its officinal preparations and dose of each; describe its physiological actions, and state the therapeutical indications for its use. 2. Give the officinal preparations of the mineral acids and doses of each; describe their physiological actions, and mention the therapeutical indications for their use. 3. Give the source and composition of guaiacum; name its officinal preparations and doses of each, and describe its physiological actions and the therapeutical indications for its use. 4 Give the officinal preparations of silver, with doses of each. Describe its physiological actions, and mention the therapeutical indications for its use. 5. Give the source and active principles of ergot; name the officinal preparations and describe its physiological actions, and state the therapeutical indications for its use. 6. Give source and composition of erythroxylon; name its officinal preparations, and describe its physiological actions, and state the therapeutical indications for its use. 7. Describe the physiological actions of the bromides. 8. Give source and composition of gelseminum; name its officinal preparations and dose of each and describe its physiological actions and the indications for its use. 9. Describe the physiological actions of salicin and its derivatives.

Hygiene.—1. What amount of fresh air per minute should be furnished for each inmate in school-rooms, audience-halls, etc.? 2. What are the effects of exercise on the lungs? 3. What are the possible disadvantages of hot-air furnaces, and how may they be overcome? 4. What is the source and the nature of organic impurities in drinking-water? 5. What can you say of the composition and of the merits of rain-water for drinking purposes as ordinarily stored? 6. What are the advantages and the disadvantages of leavened bread as an article of diet? 7. What is the relative amount of potential energy in the following proximate alimentary substances: Dry albuminate, starch, fat, cane-sugar? 8. By what ordinary means may milk be preserved for a limited time without ice? 9. In purifying an infected apartment by burning sulphur, what quantity of sulphur in proportion to the size of the room would be sufficient? 10. What, in your opinion, is the best method of disposing of excreta? Give your reasons.

PULMONARY CONSUMPTION IN THE LIGHT OF MODERN RESEARCH.[1]

BY STEPHEN SMITH BURT, M.D.,

PROFESSOR OF CLINICAL MEDICINE AND PHYSICAL DIAGNOSIS, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING PHYSICIAN, OUT-DOOR DEPARTMENT (DISEASES OF THE CHEST), BELLEVUE HOSPITAL.

WHILE more than fifteen per cent. of all deaths in the civilized world can still be traced to pulmonary consumption, no further apology is necessary for discussing this subject. Such a mortality alone is sufficient reason for us to persevere in our efforts to trace out the source of this evil, and to devise some radical means for its prevention. Moreover, the renewed interest which recent discoveries have awakened in general medicine is fully shared by this particular malady, and a fresh impetus has been given toward the solution of a problem which hitherto had seemed almost hopeless. Nevertheless, I must confess to some diffidence in debating this theme at a time when so many startling revelations are being made in regard to the etiology of disease, and when, from this unsettled state of our science, an argument based upon a premise of to-day may turn out to be illogical in view of the discovery of to-morrow. Still, a sufficiently large number of facts appear to be conclusively established to justify our consideration of the germ-theory in its relation to pulmonary tuberculosis. I therefore undertake this topic without promising any special novelty, for my work is in the field rather than the laboratory of medicine; but with an earnest desire to elucidate the various questions involved in the present aspect of the matter, and to do my share toward promulgating the latest results of modern research. And at the outset of my essay let me acknowledge the great obligations we are under to the large number of patient, painstaking workers, whose time is mostly spent behind curtains, with closed doors, peering into the but recently explored land of the bacteria, the dark continent of infection, whose miasma has been exhaling disease and death from a poisonous vegetation heretofore undiscovered.

There is a trait peculiar to a mind imbued with the real scientific spirit which is especially commendable. No seeker after the truth feels it incumbent on himself to uphold a claim which has been proved untenable. Demonstrate the fallacy of an hypothesis and it is immediately thrown aside for one that will bear verification. Meantime, however, the imagination plays a most important part in the progress of scientific investigation; for some of our most useful discoveries have long anticipated their final confirmation. An idea, but vague in its inception, ere long assumes definite shape, and is grasped by the progressive few, only to languish in the uncongenial atmosphere of general indifference, until some more fortunate observers find the profession at large prepared for its acceptance.

From the period of Galen down through the history of medicine the infection of phthisis had been surmised at various times, until Villemin, Cohnheim, and others showed that tubercle is inoculable, and, finally, the involved data were disentangled by Koch, in the separation and culture of micro-organisms, and the tubercular bacilli, wholly freed from complicating material, were categorically proved the cause, without which no tubercle is possible. Granting that "all germinal conceptions are the product of their age rather than of any individual mind," it assuredly fell upon this distinguished biologist to be the spokesman of his generation.

To me the germ-theory is a very fascinating explanation of the mystery that formerly enshrouded many of our fatal maladies. Furthermore, the brilliant results that have been achieved in surgery, through the operations of Lister and his followers, upon this hypothesis, are most convincing proofs of the correctness of so wonderful a conception. And though we may never be able to do more than utilize our newly acquired facts in the avoidance of threatening trouble, yet who can foretell the good that will accrue to man therefrom, when he comes, as in time he must come, to an adequate realization of its importance. Nor need we relinquish the hope that industrious experimenters will some day discover the secret of bacterial warfare, so that innocuous germs can be marshalled to drive the disease-producing fungi from the field. Seeing that micro-biologists already have ascertained that many bacteria inhabit the animal tissues which are in no way injurious to them, and also have remarked the same struggle for existence in the realm of microscopy that obtains between plants and between animals in the macroscopic world, and, moreover, that repeatedly benignant germs have succeeded in overpowering the pathogenic variety, and have caused their extinction, it is not a very improbable conjecture that, in the near future, these allies of the human race may be separated, cultivated, and impressed into our service to extirpate those hostile species.

That new ideas often should meet with stout opposition, solely on account of their novelty, seems to those convinced of their worth profoundly discouraging. But may not this be a fortunate circumstance, even though fraught with some delay? for in the end a rational mean is frequently the outcome of two irrational extremities. And in the workings of nature time apparently is of very little consequence.

The great mortality resulting from pulmonary tuberculosis is shorn of some of its terrors by the duration of the malady. Were the annual deaths from this affection to occur in the course of a few days, instead of a year, the public would require no urging to be convinced of the absolute need of strictly observing preventive measures. For tuberculosis is a preventable disease, and one of the unnecessary afflictions of the human race. And man, in reality, is his own worst enemy, because, in the blindness of his ignorance, or the culpability of his selfishness, he goes about spreading disease and death for himself and his fellow-man

All forms of phthisis probably are due to the presence of tubercle, in varying proportions, and all tubercle is the outgrowth of a microscopic, disease-producing germ known as the bacillus tuberculosis. Without this parasitic plant, however depraved the constitution, there will be no tuberculosis, and also, fortunately, with this morbific agent there will be no phthisis, unless the vitality of the tissues is impaired.

These liliputians of the vegetable kingdom are dwellers in a shadowy land, in which their forms and habits are being studied through magnifying media, wherewith the inventive mind of man has supplemented the natural limits of his vision. And soon, by the aid of photography, we may be able to dip, nay, have already dipped, more deeply

[1] Read before the Section in Medicine, New York Academy of Medicine, Tuesday, March 18, 1890.

into this obscure region than the human eye can penetrate.

Taken in through the inspired air or by means of contaminated food, these infusoria are distributed throughout the body, and find lodgement at points of least resistance, where they become foci of irritation and provoke a modified inflammatory process, which results in the development of tubercle. But the mere introduction of these bacteria into the system will not invariably cause tuberculosis, since healthy tissue as a rule repels any attempt of the germs to establish themselves, and, were this not so, humanity ere now would have been exterminated.

The bacilli, or their putrefactive products termed ptomaines, enter the circulation, and by their effect upon the heat centres cause an elevation of temperature, which is an outward expression of the inward conflict that is being carried on to expel the poisonous principle, and as all nature is rhythmical in its action, the fever partakes of this inherent character. Hence the cessation of the pyrexia is a sign of the inactivity of the fermentation, and if the organic structures have not suffered too great havoc in the struggle, recovery from the affection may take place; but if the tissues are extensively destroyed, death may ensue from the inability of the patient to survive the disorganization. Thus the famous saying of Niemeyer, that the greatest danger for the majority of consumptives is that they are apt to become tuberculous, must undergo revision in the light of recent developments; for the greatest danger now threatening mankind is that cells of a retrograde metamorphosis may chance to encounter the tubercle bacillus in its wanderings.

Bacteria abound in enclosures and in densely populated towns, whereas they are not found, especially at great elevations, in the open country. Likewise phthisis prevails to a much greater extent in the cities than in rural districts, and among the sedentary than amid those otherwise circumstanced, and, practically, the disease seldom exists at high altitudes. Domesticated animals that are crowded together and wild beasts confined in cages often die of tuberculosis. So, also, soldiers packed too closely in barracks, and inmates of prisons with insufficient breathing space have an excessive mortality from consumption.

While we believe that the germs of tubercle are not often directly transmitted to offspring, nevertheless, degraded cells enter into the new organisms, which form an inviting nidus for the ubiquitous bacillus. If it is true that each of the millions of cells that constitute the individual has a representative in the protoplasmic matter which combines for the evolution of the succeeding generation, then it is not strange that the cells which go to make up the lungs in another development should be relatively deficient in vitality. There is no difficulty in comprehending inheritance among some of the lowest forms of life, for the homogeneous body of the parent simply divides in two or more parts, a process called fission, and ceases its personal existence, while the descendants continue their separate lives, similar in every respect to the proximate ancestor. But, when we rise to the more highly evolved and differentiated animal texture, where each cell has its special function, and all cells a mutual dependence, such self-division would be fatal alike to parent and child. Hence the hypothesis of an assemblage of physiological units representing the entire fabric of the body in the sperm-cell and germ cell of the progenitors, whose integrity in this process is practically maintained. This comprises all there is of the so-called inheritance of phthisis. On the other hand, an acquired insecurity from the pathogenic germ is due to innumerable causes which conspire to lower the tone of the system in general, and of the lungs in particular. One source of structural weakness which has especially impressed me is that the waste products circulating through the organism are ofttimes not properly oxygenated on account of defective respiration, and these form an attractive field for the harmful bacteria; whereas, a thorough daily bath of the tissues in well-purified blood consumes the ptomaines, and by keeping the cells of the body in a sound condition starves the germs that have chanced to gain admission. Furthermore, in my opinion, some of the undefiled animal fluids alone are the best germicides. An illustration of the probable truth of these suppositions is the marked infrequency of phthisis in those who lead active outdoor lives as compared with persons of sedentary habits, and, while it is partly to be explained by the increased danger of infection in the latter, still, the other element in the causation is not always sufficiently appreciated.

I must devote a moment, in passing, to the very ingenious and interesting interpretation of one of the supposed functions of the white blood-corpuscles. They are thought to exercise a sanitary supervision throughout the frame, and, whenever poisonons ptomaines or disease-producing germs lodge therein, these guardians of the vital economy rush to the place of danger, and there, closing about the intruders, endeavor to destroy them, and thus protect the system from noxious invasion. Whereas, opposing this ingenious answer to a very perplexing question, follows the assertion that these leucocytes do not kill the bacteria, but that an innate though varying germicidal power exists in the healthy blood-serum, while the white corpuscles are, in a limited degree, the scavengers, as it were, rather than the custodians of the tissues, and this belief is more in harmony than the former one with the theory which I previously advanced.

Now let us consider what would naturally follow if this little micro-organism is, what many believe it to be, the exciting cause of phthisis. It is found almost constantly in large numbers, among the material coughed up by diseased subjects, and it is known to retain its vitality for varying periods after desiccation; consequently, there is every reason to suppose that the bacteria floating in a fine dust about the air, more especially of a room, would find their way by inhalation into the lungs. Also, they might fall upon an abraded surface and be carried into the circulation. Likewise, they would settle upon articles of nutriment and be taken into the stomach, and thence, by absorption, into the system. Further, tuberculosis taints some of the many animals utilized by man as food, and the bacilli are found in the milk of infected cows. Therefore, these germs might be introduced into the system with underdone meat and in milk that has not been boiled.

Wherever the population is most dense, there the disease ought to prevail, and particularly among the poor and the ignorant of our community.

Again, conversely, what has been revealed day by day, to verify these inductions? Long before the discovery and cultivation of the micro-organisms, pulmonary consumption was conveyed to the lower animals by inoculation.

Dust taken from the walls of rooms in private houses and public hospitals, occupied by phthisical patients, in the same manner, has been productive of tuberculosis with these helpless victims of scientific investigation. Then of a number of dogs made to inhale the dried sputa of consumptives, a few became infected within three weeks, and, ultimately, all gave evidence of the malady. What is more, the disease has been induced in rabbits, lambs, and swine by milk from diseased cows, and several animals have been contaminated through feeding upon meat that was tuberculous. Finally came the isolation and tillage of the specific bacillus already noted, which still caused phthisis when introduced into the system under favoring conditions.

The death-rate from tuberculosis in some cloisters has been as high as fifty per cent., and in many prisons it has risen above sixty per cent. And the loss of life from this cause among manufacturers is said to be twice as great as that of agriculturists.

After many years of regular, though not constant, relations with phthisical patients, my experience leads me to the conclusion that either the disease is never contagious in the common acceptation of the term, or else the physi-

cians whom I have known under similar conditions to myself are especially exempt from such influences. And the former seems the more rational conclusion; but, on the other hand, it has been amply demonstrated that persons living in permanent intercourse with these patients often become infected with the disease. Moreover, the examples of its dissemination under these circumstances are too frequent to be accounted for by mere coincidence. Indeed, the mortality among nurses between the ages of fifteen and twenty is shown by Cornet to be six times greater than that of the entire population.

The well-known experiment of Trudeau aptly illustrates certain points I am desirous of making clear, therefore I briefly touch upon his investigation. Some rabbits inoculated by him with the tubercular bacilli, and placed in relations deleterious to health, became tuberculous. Another group of these same rodents, likewise confined, but not subjected to infection, did not develop the disease. While still another group, like the first, inoculated, yet not put in a similar situation, but, on the contrary, favorably located as to hygiene, mostly escaped the malady.

Enlarging upon the mortality of phthisis, in order to emphasize the importance of an intelligent and systematic prophylaxis, we must not lose sight of the fact that this affection is somewhat self-limited, and that it has not infrequently blazed up, or smouldered for a time, and then died out for lack of fuel. So that the death-rate in proportion to the number of cases, could they be known, is not, after all, so alarming. And that the bacteria do not multiply outside the animal body, and that the breath of human beings does not, as a rule, contain these microorganisms, are facts in favor of the limitations of the virulence of the malady.

With regard to the detection of the disease in the beginning of the course, I must confess that our resources are circumscribed, and that, at this stage, the history and symptoms bear an equal if not a greater weight than the physical signs upon the results of our examination.

In the treatment of pulmonary consumption we have two factors to consider, namely, the predisposing and the exciting causes, and one is as momentous in its effects as the other.

There is a truism common to all living things from the lowest to the highest: existence cannot long continue without food, and the food of the tubercular bacilli are the debased blood and tissue which have been inherited or acquired. To mitigate a baneful inheritance and to regenerate a vital decadence are the indications on one side, while, on the other, the bacteria not only must be deprived of sustenance within, but also actively pressed to extermination outside the human organism. It seems to me, at this epoch of things medical, a mistaken and too hasty generalization to conclude that, after the bacilli have entrenched themselves in the system, that their destruction can be accomplished without, at the same time, destroying their entrenchment. First, then, comes the subject of inheritance, about which a strange lethargy appears to have settled upon mankind. The stupid disregard that is still shown by many to the entire physiology of animal life is only excelled by the appalling consequences that overtake the innocent martyrs to parental negligence. A man with a tubercular family history, and possibly a phthisical diathesis, should be made to understand that he is a potential source of much sorrow and misery if he selects for a wife a woman with a similar record and constitution. Contrariwise, an intermarriage with a family free from all such predispositions will do not a little to curb that downward tendency. Therefore a child with good blood for a legacy, even from one parent, has every reason to expect immunity from the disease, if he is reared intelligently. Such children must be properly clothed, very carefully fed, and encouraged to spend the greater part of their daily life in the open air, and not in the too frequently ill-ventilated school-room. Probably nothing is more conducive to the complete renovation of the inner man than horseback riding. Vocal gymnastics is another useful exercise for the same object. And the regular practice of deep breathing with closed mouth out-of-doors, for both child and adult, while the bloodstream is coursing through the veins, is a purifier that is equalled by no drug in existence.

The necessity of destroying the expectoration of consumptives is imperative, because the dried sputa still contain bacilli in great numbers, which lodge in every corner and cranny of a house, whence they are stirred up and inhaled by the patient as well as his associates. While rigid adherence to a thorough disinfection of all clothing and utensils exposed to contamination will reduce the danger of close companionship to a minimum, nevertheless, the only absolute safety lies in segregation; seeing that, to occupy the same bed, or merely the same sleeping-room with a sufferer from this disease is to court a similar fate if not to insure it.

Our legislators would do well to investigate an impending danger from the laxity in the inspection of cattle and milk, for upon the nature of the food-supply depends the health of the citizen and the welfare of the commonwealth. In fact, the old saying that an ounce of prevention is worth a pound of cure has lost none of its significance in the developments of bacteriology.

Although we have no drugs that will cure pulmonary consumption, yet we are in possession of many useful remedies for its trying symptoms. And, dealing with the disease, it is of primal consequence to keep in view the goal for which we may reasonably strive, namely, to elevate the tone of the tissues and the fluids that bathe them to a sanitary pitch, where they themselves are the best of germicides. Bacteria do not thrive upon such nourishment.

An explanation of the fact that rapidly gained fatness is not always attended by a like increase in the strength of a phthisical subject is found in the statement that this kind of accumulation implies physiological impoverishment, and, associated with it, there is often a deposit of oil in the tissues, where there should be more highly vitalized elements. That is to say, obesity is accompanied by more or less fatty infiltration, if not degeneration.

Migration promises much for a patient, but I desire to distinctly state my belief that there is nothing which can be deemed specific in any climate. Moreover, what special influence certain regions will have upon the individual cannot be foretold with that precision often attempted by the over-confident practitioner. To be sure it does not appear unreasonable to suppose that a mild sedative atmosphere is best suited to a delicate, highly nervous organization, which naturally shrinks from the all-important out-door life in the low temperature of the highlands; and, contrariwise, a vigorous, phlegmatic subject of tuberculosis in its early stage would do well in the clear, cold, bracing weather of a mountainous country. But, notwithstanding all this, experience produces very anomalous results, inasmuch as one of the most remarkable recoveries from phthisis that I have known occurred in a charity patient at my clinic in the not over-salubrious air of New York.

Solar light and heat are the sources of all life, and just in proportion as plants or animals are deprived of the sun's rays they become deficient in vitality. Consider, for instance, the low grade of human development in the Arctic regions. A majority of the natives are so busily engaged in converting food into the heat essential to simple existence that all higher physiological and sociological evolution is dwarfed by the struggle. The stimulating effects of cold, combined with the all-vital sunlight, is undoubtedly of benefit to those sufficiently vigorous to respond to the stimulation. On the other hand, the balmy air of a more temperate zone, also purified by these life-giving rays, is not infrequently best constituted to restore the lost strength of sufferers from consumption. Hence we find that some improve in a cold, others in a warm climate, and there is no tangible reason because one person prospers in a place that another will have the same

experience. Even the dampness of a sea-voyage, provided the ship is well ventilated, does not outweigh the benefits of unlimited pure air. Still, I would enter my protest against the indiscriminate sending of patients from home and its comforts. The annoyances of travel, and the depressing effects of an enforced absence from one's fireside, oftentimes hasten rather than retard the onward progress of a malady already, perchance, too far advanced toward a fatal termination. Furthermore, banishing a patient to some place barren of everything but climate not infrequently defeats the purpose of the change, so slight is the opportunity for suitable diversion. And now and then consumptives are demoralized beyond measure at sanitaria by daily contact with those suffering with the same complaint.

In conclusion, let me briefly reiterate what I have been endeavoring to prove, that phthisis pulmonalis is an infectious disease, only the soil must be fertile or the bacteria will not take root and grow; that the inheritance of the affection is simply the descent of the degraded cells presenting a vulnerable point for a possible encounter with the vagrant germs. That all specific treatment is futile, in view of our present knowledge; and though persistent destruction of the infectious matter is our best means of prophylaxis, yet to restore the vitality of the lung-tissue is as important as to destroy the tubercular bacilli. And, moreover, not a few cases of phthisis have a self-limitation, which is a comforting thought for whoever is afflicted, while, at the same time, it is a disquieting reflection for the numerous noisy advocates of the very latest unfailing remedy.

37 West Thirty-second Street

STUDIES IN THE DECIDUA AND RETAINED MEMBRANES OF THE OVUM.

By EDWARD A. AYERS, M.D.,

Lecturer on Obstetrics in the New York Polyclinic.

In my investigations with the microscope of retained membranes I desired to note some of the changes leading to death of the ovum, its retention, and consequent alterations. The main points I claim to have observed are: First, transformation of the epithelia in the utricular glands in some portions of the decidua into decidual tissue; second, an inflammatory process in the avascular amnion, which I term amnionitis; and third, decidual hyperplasia.

Case I. *Retained Decidua, showing Transformation of Epithelia in the Utricular Glands into Decidual Tissue.*—The metamorphosis here observed, involving as it does the mooted question of the limitations in epithelial tissue transformations, deserves a minute and conscientious description.

In a normal uterine mucous membrane we find, previous to menstruation, the base embedded in a muscular stratum of great thickness, as compared with the same in other organs. Previous to the first menstruation the middle stratum or corium is about one millimetre (one-twenty-fifth inch) thick.

After the first menstruation it becomes permanently about two millimetres thick. It is composed of loose vascular connective tissue containing few fibres but much structureless interfibrillar substance, and has scattered through it very numerous, round, fusiform, or irregularly shaped granular nucleated cells. The inner surface is lined by a single layer of columnar ciliated epithelia. The numerous tubules or utricular glands which open into the uterine cavity pierce this layer at different angles; not as drawn by Weber, and since so often copied into various text-books, where they appear as straight parallel tubes entering the uterine cavity at right angles, but usually at an angle of about forty-five degrees, though the most conspicuous feature is the irregularity of their arrangement. They branch as they go deeper into the mucosa, where they are very irregularly distributed. The walls of the utricular glands are composed of a very delicate fibrillar tissue, arranged concentrically and attached externally to the interglandular connective tissue. Internally is a single layer of ciliated columnar epithelia, unenucleated, continuous, and apparently indentical in structure with the columnar epithelia lining the free surface of the uterine cavity. The epithelia in the glands are attached to one another by a transparent intercellular cement substance. They are generally uniform in shape and size.

Preliminary to the menstrual flow there is a marked growth in the interglandular connective tissue, the mucous membrane becoming from three to six millimetres thick; the lymph-channels widen and the glands become longer, wider, and more patulous; the blood-vessels become overdistended and either extravasation or diapedesis follows, probably extravasation. So far authorities agree. According to Kundrat and Englemann fatty degeneration of the glandular epithelia the inter glandular blood-vessels, and the connective-tissue corpuscles follows the superficial desquamation of tissue. This fatty degeneration is limited by them to the superficial layers of the mucosa, the new mucous membrane arising from the intact deeper layers. Leopold opposes the theory of fatty degeneration, while Williams holds that the entire mucous membrane is removed at each menstruation, the new membrane being regenerated from the muscular coat.

As against Williams' view, Klebs and Heller holds that the epithelium of mucous membranes is reproduced only so long as the deeper layer or matrix of epithelial cells is intact, and that when these are destroyed the cells at the margin fill in the gap, and if the marginal epithelia are also wanting, the space becomes occupied by cicatricial tissue.[1] In short, it is a general law that like tissues produce like tissues, or the space is occupied by cicatricial connective tissue.

Self-regeneration of striped and non-striped muscular tissue has been shown, through the researches of Kraske, Erbkam, and Heidelberg,[2] to occur to a limited extent, but not the regeneration of mucous from muscular tissues. If now the epithelia of the utricular glands be considered as a tissue distinct from decidual tissue, in the sense of the general law of regeneration just given, it follows that that law must have exceptions or that I have incorrectly interpreted the observations I am about to describe. On the other hand, decidual tissue and epithelial tissue may not be distinct in the sense of that general law, in which case no conflict will be resultant. Passing now to special observations of my own, the membranes I examined were from specimens obtained by Dr. Boldt, who curetted the uterine cavity of a girl, twenty years of age, she having recently aborted. The decidua was of about two months' growth. The specimens I examined were stained in ammoniacal carmine and mounted in glycerine. With low powers of the microscope the presence of utricular glands is readily recognized, characterized by the lining of the columnar ciliated epithelia and a distinct calibre, both in transverse and oblique sections. A large number of sinuous venous cavities is likewise present, varying in size and mostly filled with disintegrating blood, composed of granules of a greenish color, owing to their preservation in a chromic-acid solution. As some of the smaller veins contain unchanged blood-corpuscles, it is reasonable to believe that the circulation in the veins holding disintegrated blood had ceased some time before the removal of the membrane, and the changes incident in thrombosis occurred.

Between the glands and the venous cavities is a well-pronounced decidual tissue of the myxomatous type, traversed by a moderate number of capillaries, most of which contain unchanged blood-corpuscles. The myxomatous net-work of the decidual tissue varies in size in different places, being small around the veins and wide in the portions between the veins at the periphery of the

[1] Landois and Stirling, p. 402. [2] Ibid., p. 403.

nodule (see Fig. 1). The "decidual cells" of Friedländer or Kölliker, termed by Hirst "enormously enlarged young connective-tissue cells," occupy the greater portion of the interglandular space.

The utricular glands seen in Fig. 1 all show more or less alteration from a normal outline. They are all much enlarged as compared with those in the endometrium previous to impregnation.

In those portions of the glands where no structural change has taken place the columnar epithelia show the

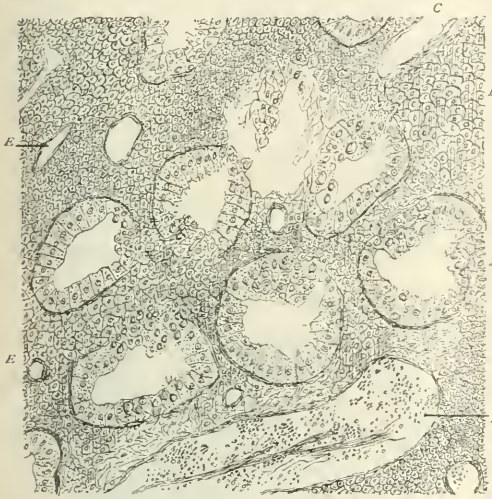

FIG. 1.—*A*, Utricular gland; *B*, decidual tissue; *C*, empty vein; *D*, vein filled with disintegrated blood; *E*, *E*, capillaries of decidual tissue.

characteristic features of form and arrangement, and are possessed of single nuclei of large granular appearance. The cell substance has a granular appearance finer than that in the nuclei. The cilia are not preserved, having been lost in the preparation of the specimen. Surrounding the epithelia is a circular band of delicate fibrillar tissue, termed anhistous or formless by Velpeau, which is continuous in the unchanged portions of the glands, being interrupted or lost in other parts. The calibre of the glands is changed as the epithelia have become altered. In the altered portions of the glands the changes noted are as follows: In the columnar epithelia a varying degree of change in form and construction is seen, so that they are no longer "columnar" but most irregular in shape and have become more or less divided and subdivided. The unusual arrangement of single nuclei has disappeared, but each subdivision of the cells now holds a nuclear body more homogeneous and refractive than the original nucleus. Where only a limited part of the epithelial ring is involved in this change the free inner margin of the cells extends or bulges and occupies a portion of the calibre of the tube, thus rendering the cavity sinuous and irregular. At the same time the outer boundary line, the circular anhistous tissue, is lost, and the altered epithelia appear to be morphologically similar and continuous with the adjacent decidual tissue. Where the tissue change has involved a majority of the epithelia, the calibre of the gland is invariably reduced, as if by compression. In the highest degree of this change only a vestige of the calibre is left, which then disappears, being filled with decidual tissue. These changes obviously lead to a destruction, as such, of the utricular glands and deserve our most careful attention. With higher powers of the microscope the gradual changes of the utricular glands, particularly the epithelia, can be traced to their complete disappearance through metamorphosis. In Fig. 2 is shown a utricular gland magnified five hundred diameters. In a considerable portion of the tubule the columnar epithelia are essentially unchanged; they retain their usual form, are possessed of single nuclei, showing the coarse granules with finer granules entering into the construction of the "cell-substance." The lateral union of the epithelia shows a double line with the interspace filled with the so-called "intercellular cement substance." At their base is the anhistous tissue which forms the outer boundary of the tubule. In the remaining portion of the tubule a generative change has begun in the epithelia; they have lost their regularity of form, have become divided and subdivided. The intercellular structure is in a transitional stage, being reduced to a single line of division and the single nuclei have given place to many nuclei of varying appearance, size, and location.

There is now to be seen a multinuclear protoplasmic mass, representing an increase in tissue, as is shown by its encroachment on the calibre of the tubule. The increase in size, and especially in number, of the granules or new nuclear bodies in place of the previous nuclei is marked. These bodies are recognized as "mother-cells," the term for endogenous new formation in epithelia. This latter process is understood to mean a splitting up, or better, a division of, and increase in, living matter in the nuclei of epithelia—that is, karyokinesis. This process, in addition to the views of Schumann, is now, owing to the more recent researches of Bütschli, Flemming, Van Beneden, Waldeyer, and others, recognized as one of the most important biological discoveries of the past twenty-five years, particularly on account of its relation to fertilization of the ovum. This process invariably occurs in inflammatory and other changes in epithelia, leading either to a new formation, or growth, or a reduction into a medullary or embryonal condition of the epithelial tissues. Not infrequently light, so-called plasmatic spaces surround the newly formed granules or nuclei. Observing further we see the second stage, the so-called medullary or embryonal, in which the epithelia break up into nucleated protoplasmic bodies, varying in size, and

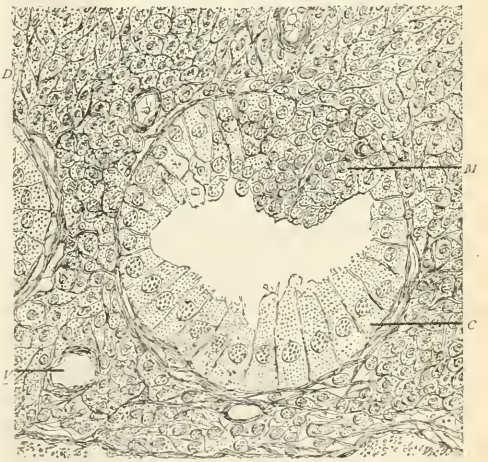

FIG. 2.—*C*, Columnar epithelium of utricular gland, unchanged; *M*, epithelium transformed to medullary tissue; *D*, myxomatous decidual tissue; *V*, capillary blood-vessel in transverse section.

separated from one another by light lines of an intercellular cement substance. This cellular division is seen to be most complete in the more central parts of the changing tissues, and only partial at the junction with unchanged epithelia. The intercellular cement substance shows in its construction a certain amount of living matter, and by a consolidation produces the myxomatous

reticulum, while the original medullary bodies have grown up into nucleated so-called "decidual cells," now considered as protoplasmic masses filling the meshes of the myxomatous reticulum. I have mentioned that in places at the periphery of the tubule, where the transformation of the epithelia is going on, the bordering line of the utricular gland is lost, and the medullary tissue sprung from the epithelia blends without demarcation with the adjacent decidual tissue, as is shown in Fig. 2.

Decidual tissue is generally admitted to be myxomatous connective tissue. Most modern microscopists limit the variability of epithelial tissue to such a degree that only epithelial formation can be derived from it. It is clearly shown in my specimens that there is a transformation of the glandular epithelia through an intervening stage of embryonal or medullary into decidual tissue.

The objection may possibly be raised that I have misinterpreted the changes observed; that the transformation was one of proliferation of the extra-glandular decidual tissue and its substitution for the epithelia. The alteration in the epithelia was not a degenerative or destructive process, no desquamation had taken place. The various grades of endogenous new formation in the epithelia can be clearly seen. Nor does the circular anhistous tissue, which surrounds the glands and stands as a barrier between the epithelia and the outer decidual tissue, disappear until the alteration in the glandular epithelia is well advanced.

On the other hand, it cannot be claimed that the specimens here described permit the claim that all decidual tissue arises from the glandular epithelia. Ercolani[1] holds that the human decidua is, for the most part, a product of exudation from the utricular glands. The "epichoreal" decidua (reflexa) has no utricular glands.[2] They are present in both the "placental" decidua (serotina) and "uterine" decidua (vera), but remain open longer in the former than in the latter, where they are finally found only in the deeper layers.[3] It is probable, therefore, that the specimens herein described are from the decidua uterina or vera.

How do the statements here made harmonize with our present knowledge of tissue regeneration?

Without attempting an extended answer to this question, I wish to suggest a few points. Quoting from Professor Marcy:[4] "Except as viewed by Ercolani, the opinions which have been entertained concerning the origin of the cells which enter so largely into the formation of the maternal portion of the placenta have been exceedingly vague and uncertain. Professor Turner, although concisely affirming, with Owen, that without decidua there is no formation of placenta, does not touch the important question of the origin of the decidua. Professor Kölliker confines himself to the remark that the decidua is a transformation of the uterine mucous membrane, and not a new membrane or the product of an exudation, as was once believed. It may be observed, however, that Professor Kölliker does not attempt to show which are the elements in the mucous membrane that compose the decidua, nor by what means they are transformed, although such an investigation should be of the highest interest to him, since the glandular follicles of new formation, as demonstrated by Professor Ercolani, and largely confirmed by Turner, were only declared by him to be tunefactions of the pre existing uterine mucous membrane, formed during pregnancy and disappearing after delivery."

As a rule, the glandular epithelia of mucous membranes, derived from the internal layer of the blastoderm, perform their chief physiological function by entering in, following desquamation, as an essential part of the secretion poured out by the glands, as in the lactiferous glands, for example. In the utricular glands, however, the secretion during non pregnant periods is an indifferent mucus having no nutritive function. I agree with Dr. Putnam Jacobi,[5] that "since it is from the epithelium (the original hypoblast elements) that the serotina or 'glandular organ' of the placenta is formed, and since it is the epithelium from which the entire mucosa is regenerated, both after parturition and after the less severe exfoliation of menstruation, it is evident that the epithelium is of great importance among the elements of the endometrium. The epithelium of the glands is simply a prolongation of that lining the cavity in a series of convolutions. From this point of view these glands may be considered simply as folds of epithelium, convoluted as is the surface of the brain, by the usual organic device for multiplying extent of surface within a given space." Comparative anatomy and physiology present facts that favor this view. For example, the hare has no utricular glands—simply crypts lined by involutions of the surface epithelium.

A comparison of the conditions present in extra-uterine tubal pregnancies with those of intra-uterine, gives striking evidence in favor of the views here expressed. Here we can eliminate the "different species" equation, and obtain some knowledge of essentials in gestation. The Fallopian tubes have no glands, but an extensive

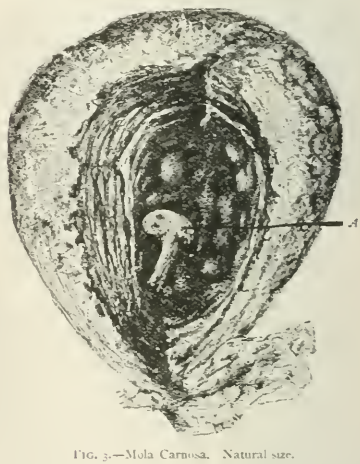

FIG. 3.—Mola Carnosa. Natural size.

surface of involuted mucous membrane resting upon a muscular base. The free surface of the mucous membrane, which if stretched out would be very extensive compared with the space it occupies, is lined with ciliated columnar epithelium, differing in no way apparently from that lining the endometrium, except that the cilia move in the opposite direction, each moving in the direction of the cornua. Notwithstanding the absence of any glandular arrangement in the tubes, a successful gestation is quite possible. Nor is the customary premature termination of gestation by hemorrhage or rupture apparently due to the inability of the mucous membrane to perform its share in the unusual gestation.

The utricular glands cannot be said to be essential, then, as glands whose function is to supply a secretion or excretion, and doubt may fairly be cast upon the theory of Ercolani, that the decidual tissue is for the most part a "product of exudation from the utricular glands."

CASE II. *Fleshy Mole: Decidual Hyperplasia and Amnionitis.*—The specimen obtained in this case, which was presented to me by Dr. McGillicuddy, is of unusual occurrence and interest, and justifies some special attention clinically as well as microscopically.

Mrs. M— —, aged thirty-four, married five years, had two children and afterward two miscarriages. Her first

miscarriage occurred in February, 1888, at two months' gestation. Menstruation was resumed the following 12th of June. Impregnation followed. Morning sickness developed during the latter part of July. August 10th, a uterine hemorrhage ensued, supposed to have been caused by lifting a heavy trunk. The hemorrhage lasted three days. No pain was experienced. Hemorrhages followed on September 9th and November 8th. The latter lasted seven days.

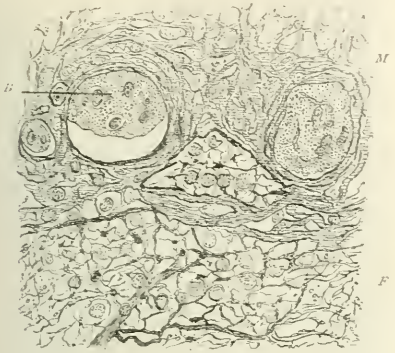

FIG. 4.—*B*, Protoplasmic buds; *F*, coagulated fibrine: *M*, hyperplastic myxomatous reticulum of decidua.

when, preceded by severe pains, the specimen shown in Fig. 3 was passed from the uterus. A segment has been removed to show the cavity, in which is seen, in natural size, a fœtus of four weeks' development, attached to the wall of the ovum by the allantois.

From the history and the stage of development shown by the fœtus, its death must have occurred in August with the first hemorrhage. It is somewhat remarkable that during the three months in which it was retained, no absorption of its tissues took place. The cavity in which the fœtus floated was lined with a smooth, but nodular, corrugated membrane—the amnion. The dense tissue composing the wall or body of the mass was traversed with clotted blood; the latter, indeed, representing the greater part of the mass. Nevertheless, it is more properly termed a "mola carnosa" than "mola sanguinea."

Although the embryo died at the end of four weeks

FIG. 5.—Diffuse Hyperplasia of Decidual Endometrium. — 500.

yet the placental tissue continued to develop, pathologically, up to the time it was expelled.

The mounted specimens prepared from it, if viewed with low powers, show the main mass consisting of blood-clot; in some places with masses of red blood-corpuscles, in others with masses of coagulated fibrin. Imbedded in these masses are seen remnants of villosities, cut in all directions, mostly compressed and with but scanty vestiges of blood-vessels also compressed and collapsed.

The placental tissue is preserved in but few places, and in a peculiarly altered, condensed condition. The periphery is composed of the amnion-producing nodular bulgings from the adjacent decidual tissue, and greatly varying in thickness in different parts of the specimen.

Some portions of the amnion are very little changed in thickness, and in this situation are characterized by a lining of short columnar epithelia toward the cavity holding the amnion.

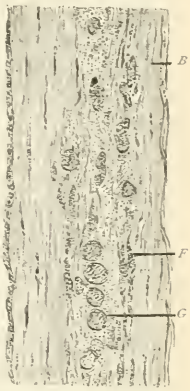

FIG. 6.—Acute Amnionitis. *E*, single epithelial cover; *B*, fibrous basis-substance: *F*, spindle-shaped protoplasmic bodies; *G*, inflammatory capsules proper.

Other portions are about twelve times as thick, and thus likewise cause irregularly corrugated and nodular protrusions. Such places show a variety of protoplasmic bodies, either globular, oblong, or spindled, imbedded in a dense striated tissue, obviously the outcome of a chronic formative inflammation. As I was able to trace the different stages of the inflammatory process from its first stage in the acute form up to a marked increase of the amniotic tissue, I am induced to describe a, so far as I know, hitherto unknown pathological process, for which I propose the term, amnionitis.

Obviously this process was caused by the hemorrhage in the underlying placental tissue, the extravasated blood acting by mere pressure as an irritating agent.

With powers of six hundred diameters the attention is first fixed upon the villi, which are imbedded in, and surrounded by, either coagulated fibrin or compressed decidual tissue.

These villi are lacking the original myxomatous tissue altogether. In its stead we find a finely striated tissue, evidently fibrous connective tissue, with a varying number of partly branched, spindled protoplasmic bodies.

This tissue could not have arisen from compression of the original myxomatous tissue, but must have come after

FIG. 7.—*E*, Covering epithelium; *F*, newly-formed fibrous connective tissue: *G*, spindle-shaped and globular protoplasmic bodies; *C*, clot of blood.

inflammatory processes that had led to the new formation of the fibrous tissue, and obliteration of the majority of the blood-vessels. It seems that some time elapsed between the advent of the hemorrhagic infarctus and the ultimate changes in the villi. In a few villi I have observed a large number of closely packed protoplasmic bodies, oblong and spindled, the only intimation of early formation of fibrous connective tissue. In a few places

I have met with transverse sections of villi, which, instead of being myxomatous or fibrous, are composed of protoplasm with a few interspersed globular or oblong nuclei (see Fig. 4). Such places were found mainly at the junction of chorionic villi and decidua.

My studies in development of chorionic villi and placental villi cause me to make the suggestion that we have here to deal with protoplasmic buds of fully formed villi in a stage of indifference. I have observed that the villi grow by sending out protoplasmic masses, either sessile or pedunculated, starting from the epithelial cover of previously formed villi. Such buds are either made up of a uniformly granular protoplasm or of a multinuclear protoplasmic mass without any differentiation into epithelia, myxomatous tissue, or blood-vessels.

Since such protoplasmic buds were found surrounded by a dense fibrin of coagulum, it is reasonable to assume that this coagulum produced a wall around the buds, protecting them against compression or further changes. It is less likely that the protoplasmic buds penetrated into the coagulum. The decidual tissue, when present, is likewise characterized by the absence of the myxomatous reticulum and the presence of a delicate fibrous connective tissue, with varying number of oblong or spindled protoplasmic bodies (connective cells) imbedded in it. Very exceptionally we meet with a myxomatous reticulum composed of broad trabeculæ with nuclei at the points of intersection.

The meshes of this reticulum show decided variation in size and contain a finely granular albuminous coagulum (see Fig. 5). Here a hyperplasia of the myxomatous reticulum seems to have developed, such as we sometimes observe in the lymphatics of the uterine mucosa in consequence of chronic endometritis.

Amnionitis.—The most striking features are seen in the inflammatory changes of the amnion. Being a non-vascular tissue it affords an excellent opportunity for the study of inflammatory tissue changes, almost as good as the much discussed cornea. Some pathologists consider tissue changes in inflammation a mooted question, looking upon inflammation as an emigration of colorless corpuscles in accordance with Cohnheim's theory. Of late this theory has lost ground, particularly in Germany. My specimens prove the presence of tissue changes with great certainty, a fact whose influence is in the direction of a broader definition of inflammation If Cohnheim is right in saying that an aggregation of leucocytes is inflammation, from whence should we imagine protoplasmic bodies in the inflamed amnion to have sprung? There are no blood-vessels, and all the blood-vessels of the subjacent placental tissue have either been compressed or destroyed by hemorrhage. The inflammation set in after this hemorrhage and there was no chance for the leucocytes to

FIG. 8.—Subacute Amnionitis. × 50. *A*, Enormously thickened amnion; *V*, *V*, villi of dense fibrous connective tissue; *C*, clots of blood.

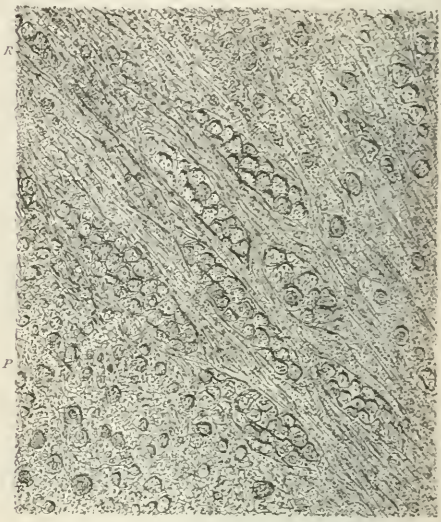

FIG. 9.—Acute Amnionitis. *R*, Rows of medullary corpuscles; *B*, slightly fibrous basis-substance in process of reduction to protoplasm; *P*, accomplished reduction of basis-substance to protoplasm.

emigrate from destroyed blood-vessels. By Heitzmann and Stricker it is claimed that both the cells and the basis substance surrounding the cells are made up of protoplasm and are endowed with life. In inflammation a liquefaction of the basis substance takes place and the protoplasmic condition reappears, leading to an increase of the living matter and the appearance of inflammatory corpuscles that are identical with those embryonal or medullary corpuscles that have originally assisted in building up the tissues (see Fig. 6).

According to Stricker, there exist no migratory corpuscles in the corneal tissues either in the normal or inflamed condition. What has been considered as such is, in reality, an alternating change of protoplasm to basis substance, and vice versa. My specimens of amnionitis show the different stages of this transformation, for we see, first, an increase in the bulbs of the connective-tissue corpuscles, next the reappearance of the protoplasmic stage of the basis substance and the splitting up of the latter into inflammatory corpuscles of wide variation in size and shape.

An inflamed tissue is largely composed of medullary or inflammatory corpuscles, which remain united with one another so long as no suppuration has taken place. Separate inflammatory corpuscles are pus-corpuscles and their sum total is an abscess. So long, however, as the inflammatory corpuscles remain connected the inflamed tissue remains a tissue and is liable to return to the stage of basis-substance. Owing to the increase of living matter the bulb of the inflamed tissue is increased, and as such represents another termination of the inflammatory process, *i.e.*, hypertrophy, or, preferably, hyperplasia. This condition of the tissue is seen as a marked thickening of the amnion, being again fibrous in structure, though supplied with a larger number of protoplasmic bodies than normal (see Fig. 7).

The sequence of changes in the tissue under discussion was first hemorrhage from unknown causes, next irrita-

tion of the amnion and acute inflammation thereof, and at last thickening of the inflamed amnion in certain parts, under the form of hyperplasia. The same process is traceable in the remnants of decidual tissue and its villosities.

The transmutation of the original myxomatous into the final dense fibrous connective tissue was certainly not a direct one, but was through the intervening stage of reduction to the medullary condition, in other words, acute inflammation.

Case III. *Subacute Amnionitis.*—The tissues examined in this case were from a patient two months advanced in pregnancy, the placental tissues or residues having remained in the uterine cavity for six weeks following abortion. On account of metrorrhagia the placental shreds were removed by Dr. Wm. Hanlock of this city. They were placed in a half of one per cent. chromic acid solution and the specimens mounted in glycerine. The image under the microscope closely resembles that of Case II. We see enormous masses of blood with well-preserved red blood corpuscles, islands of previous villi of different sizes, and the whole surrounded by enormously thickened amnion, which partly again is traversed by hemor-

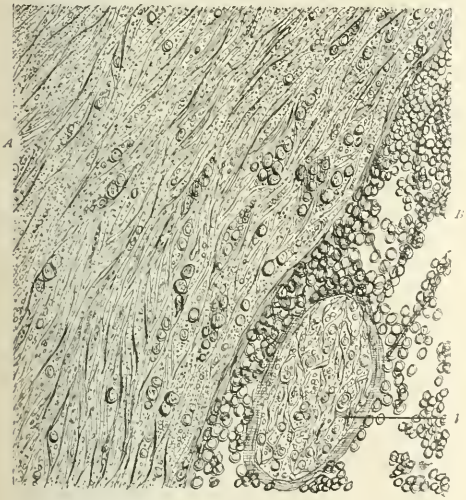

Fig. 10.—*A*, Hyperplastic amnion—dense fibrous connective tissue—protoplasmic bodies; *V*, hyperplastic fibrous tissue of a villus; *B*, red-blood corpuscles.

rhagic infarctions. With low powers of the microscope we recognize a condition of amnionitis and placentitis, more advanced even than in the previous case (see Fig. 8). Portions of the amniotic tissue are in a condition of acute inflammation, and since both the features of acute and chronic amnionitis are combined it may best be termed subacute amnionitis. In order to illustrate the correctness of the views concerning acute inflammation as explained above, I have studied portions of the amnion in an acute inflammatory state, such as were seen best in the immediate vicinity of the blood-clot, with the highest available powers of the microscope, *i.e.*, twelve hundred diameters (see Fig. 9). We see protoplasmic bodies of varying sizes, partly single, partly in clusters and rows. In the latter situation the medullary corpuscles are mostly somewhat polyhedral, as if by mutual flattening. Such rows are most conspicuous where a certain amount of delicate fibrous tissue, *i.e.*, the basis substance of the amnion, is still preserved. That medullary corpuscles may appear in the middle of the basis substance is plainly shown in the right upper corner of the drawing, in the field marked B. The fact is inexplicable, unless on the ground that the basis substance itself is viable. Life, however, is not in the basis substance at large, for we know that there is a large amount of glue-yielding substance which, as such, cannot be the seat of life. This property seems inherent only in the part of the basis substance that is traversed by an extremely delicate reticulum.

Should the glue-yielding part of the basis substance become fluid by its disintegration or liquefaction, the immediate result is the re-establishment of protoplasm in which the reticulum of living matter is seen plainer than in the basis-substance, as demonstrated in the left lower corner of the drawing at P. Here we notice mostly scattered lumps of protoplasm greatly differing in size, from a small, almost homogeneous lump up to a nucleated medullary corpuscle.

The main mass of both the amnion and the decidual tissue is in a condition that we know as hyperplasia. In this condition we see a dense fibrous connective tissue, between the bundles of which there are numerous globular bodies, the so-called connective-tissue corpuscles, in rows or clusters.

These are the remnants of the inflammatory corpuscles which, by becoming spindled, produce the basis substance (see Fig. 10). Amnion is an avascular tissue and, even in a chronic inflammation in hyperplasia, will not show any traces of blood-vessels, contrary to the cornea, which in the same condition is invariably supplied with blood-vessels growing from the periphery toward the centre. The villi likewise exhibit occasional stages of acute placentitis, though their majority is made up of a more or less conspicuous fibrous connective tissue, with an almost complete loss of capillaries. Unquestionably there must have been left a vascular connection with the decidua, for otherwise we could not understand the inflammatory changes of the placenta and amnion.

Instead of becoming necrotic or absorbed, as is the case with tissue-shreds, isolated by hemorrhage, in this case important tissue-changes have taken place which go far toward proving that nutrition of the placenta had not been entirely destroyed.

I wish to here record my indebtedness to Dr. Carl Heitzmann for the use of his laboratory, and especially for many valuable suggestions afforded during my investigations.

126 West Forty-fifth Street.

A CASE OF TEMPORARY COMPLETE AMNESIA ASSOCIATED WITH EPILEPSY.[1]

By OGDEN BACKUS, M.D.,

Rochester, N. Y.

The states of double consciousness and amnesia more or less complete, which are sometimes associated with epilepsy in its various forms, have a peculiar interest, not only from a psychological, but from a medico-legal point of view. Scattered through the whole range of medical literature, but more especially in works pertaining to psychology, are unique cases recorded where the current of normal consciousness is suddenly broken, and the individual enters, metaphorically, another world—a new field of action. He may converse, move about, and to the casual observer be in a normal condition; he has, however, no recollection of past events; the attack terminates and a reversion to the normal state ensues, with no memory for any event which transpired during the abnormal period. Instances of an amnesic condition associated with epilepsy are not uncommon. Ribot relates a case in which an educated man, thirty-one years of age, found himself at his desk, feeling rather confused, but not otherwise ill. He remembered having ordered his dinner, but not having eaten or paid for it. He returned to the dining-room, learned that he had both eaten and paid, showing no signs of being ill, and had set out for his office. This state had lasted about three-quarters of an hour.

[1] Read before the Monroe County Medical Society.

Trousseau reports the case of a magistrate who, attending a meeting of a learned society in Paris, went out bareheaded, walked as far as the Quay, returned to his place, and took part in the discussion, with no knowledge of what he had done.

Spitzka, in his work on insanity, gives the detail in the case of a policeman afflicted with epileptic insanity, who donned his badge, seized his club, and patrolled a "beat" —the wrong one, it is true—but in such a manner as to attract no special notice. He had no recollection of it afterward.

Instances of homicidal and suicidal attempt while in this state are not rare, but the case given by Dr. Clouston, of the Royal Edinburgh Asylum, is certainly, as this well-known alienist puts it, extraordinary. "A young epileptic, fifteen years of age, who was very friendly with me when he was well, used to dislike me very much when excited after fits. On one occasion the attendant found him and another patient contriving to make a weapon with which to assault me or the chief attendant, out of a stocking which the epileptic had taken off, put a stone in the toe, tied a string about this, and had then slipped it up his sleeve till he should have a chance of using it. When he got out of the epileptic condition, he was astonished when told about this, and said he had no recollection of it whatever, which I believe to be true. The combination with another patient, the combined preparation of a weapon, all in a state of epileptic unconsciousness, I could not have believed possible had I not seen it in that patient." Supposing this man had not been in an asylum, and had combined with another in preparing a weapon, waited for an opportunity, and had committed murder; and then assuming a doctor had gone into the witness-box and given evidence that the murderer was quite irresponsible, on account of being in a state of epileptic insanity, and therefore, irresponsible for his acts at the time. With what lofty scorn would the judge have set aside such evidence as being inherently incredible! With what dogmatic assertion the newspapers would point to such an example of a medical man trying to defeat the ends of justice and screen a criminal! What lively ridicule the journals would have poured upon evidence so "opposed to common-sense and to law!" And all because a fact of nature and of disease had been brought out before those who were ignorant of the whole subject. Cases of this character might be quoted indefinitely, but my object to-day is to relate the details of a case of petit-mal associated with this amnesic condition, which I had under my care for nearly two years, and therefore had an opportunity to observe its interesting features on several occasions, from the moment of the attack to its termination.

A. B——, a male, fifty-two years of age, was admitted to the State Lunatic Asylum at Utica, in March, 1885. He was married, had five children, and was a painter by occupation. His family history was good, the only member who had suffered from any nervous affection being the patient's sister, who at times had what the neighbors called the "high-strikes." The patient himself was of a nervous temperament, and always quite emotional. He was in the War of the Rebellion, and toward its close had a sunstroke, from which he slowly improved, returned home, but was considered as eccentric afterward, at times more markedly than at others. After the sunstroke, he had various intestinal and stomachic disorders, and never was in good health. Six months previous to the time when he came under my observation, it was noticed that he had "periods," as the family expressed it, "in which his nature would change;" he would wander off into the woods, have delusions of suspicion, lose all recollection of past events, and at one time made an attempt to jump from the second-story window with suicidal intent, afterward disclaiming all knowledge of the act. These paroxysms would occur from one to three times a day, and finally, while in them he became so threatening toward his family, that, as they were unable to control him, it was thought best to have him committed to the asylum. I questioned his relatives very closely for a history of epilepsy, but they were unable to give satisfactory answers to my interrogations, and insisted that he had never had a fit, to their knowledge. At the time of his admission, I made a rather hurried examination of the patient; he was in a poor physical condition, weak and anæmic; he appeared in a somewhat apathetic condition, and to all questions which referred to his past life, he invariably answered, "I don't know." He could not tell his age, where he lived, how many children he had, or give any history whatever of himself. He appeared to appreciate what was going on about him, however, and would answer any question relative to the present. He asked to go to the water-closet, was introduced to the supervisor of the department to which I assigned him, and conducted himself in a fairly rational manner. He was sent to the ward, and an inventory was taken of everything on his person; he went to the dining-room, had dinner with the other patients, and was given a bath; while in the tub, he seemed to arouse himself, the apathetic condition passed off, he asked where he was, how he came there, where his friends were, and other intelligent questions. Said that the last place he remembered was the railroad station at Utica. I visited him, and during the conversation he told me that "about three years ago he first noticed that something was wrong with his head," had "dizzy attacks," and that gradually these symptoms grew more severe, and afterward were followed by a "burning pain," especially over the occipital protuberance, and an uneasy pulsation in his stomach. Toward evening I again saw him, and his condition was similar to that on admission in the morning, although he seemed more apathetic. His eyes were turned down, pupils somewhat dilated, and there was slight anæsthesia of the skin. He went to supper, however, with the others, and appreciated what was said to him. During the next four days he had several of these attacks, varying from thirty minutes to an hour in duration. His attendant stated that he had not had a fit of any kind, but he appeared to fall from one state into the other without warning. His pulse ranged about 90, tongue coated, and there was marked tenderness of the spine, especially over the last cervical and several of the dorsal vertebræ. Slept fairly well, but appetite was poor. On the morning of the 21st, in order to test his memory, he was questioned closely in regard to his early life and incidents connected with the War of the Rebellion. He stated that he enlisted in the One Hundred and Fifty-third Regiment, New York Volunteers, and was under Captain C——, who was shot at Winchester, and the command then fell to Captain F——. That he was in the battles of Pleasant Hill, Maudsville Plains, Winchester, Fisher Hill, Cedar Creek, and various other engagements, but escaped being wounded. Was ordered to Savannah, Ga., after Lee's surrender, and while on a forced march to Frederick City, he had a sunstroke, and it was several days before he regained consciousness. He was sent to the hospital, and in a month was offered his discharge, which he refused, as he preferred to remain with his regiment. While in Louisiana he had some gastric disturbance, associated with a dull, heavy pain, which would occasionally become of a sharp, lancinating character in the region of the umbilicus. This continued during the service, and after he was mustered out and had returned home, the physicians who examined him in A. and J. said he had cancer of the stomach. There was some swelling of the right side over the pylorus, which gradually passed away. At this point, while trying to recall the names of the physicians who had made a diagnosis of cancer of the stomach, he suddenly stopped, his eyes became fixed on the floor, his pupils dilated a little, and his right hand began to twitch, and there was a slight tremor of the body. He did not respond to questions or appear to feel when touched. His pulse, which was 90 before the attack, now rose to 110, and was full and strong. This condition lasted but a moment, when he

commenced to move his head from side to side. I asked him what was the matter, but he made no reply. I then asked him if he was in the War of the Rebellion, and he said "I don't know." I asked him what his name was, and he told me. When asked how old he was, where he came from, if he had a wife or children, and again whether he had ever been in the war, his only reply was, "I don't know;" to all facts in any way relating to his past life he seemed oblivious. When asked how he felt, he said he had a severe headache. He walked about the ward, brought a chair from the next room, drank some water, and would answer questions rationally in relation to the present; for instance, when asked the number of persons in the room, the number of chairs, the state of the weather, etc., he gave correct answers, but all memory for past events seemed gone. He, however, remembered his name. This state lasted about an hour, when he regained his normal condition, complaining still of headache

During the next week he had several of these attacks, and while in one of them became quite violent and disturbed. Being convinced that the attacks were due to petit-mal, I put the patient on Hamilton's[1] epileptic mixture, and after a few days the attacks ceased; his spirits rose; he became more cheerful and contented; gained in flesh, and said he had not felt as well in years.

In another month the Hamilton mixture was discontinued, and ten days later he had an attack similar to those already described. He was again ordered the remedy, and the attacks were prevented. He progressed fairly well for a couple of months, when he became depressed, apprehensive, suspicious, restless, lost his appetite, and developed delusions, one of which was that a man was constantly pursuing him with a knife. From this time on the patient rapidly drifted into a condition of deep melancholia with suicidal tendencies, had marked hallucinations of sight and hearing, and expressed his delusions freely. Occasionally he would become violent, striking those about him. He was finally transferred to the Binghamton Asylum, as a case of chronic insanity.

I have presented this case as an illustration of an interesting phenomenon, and time does not permit of any dissertation relative to the various causes which may produce this amnesic condition.

Much chaff has been thrown into the subject, and but little wheat winnowed; but I do believe we can draw this conclusion, that in individuals charged with a crime for which, notwithstanding the evidence of their guilt, they protest their innocence and want of knowledge, a close medical scrutiny should be permitted, lest, peradventure, an unfortunate being be unjustly punished for an act for which he is totally irresponsible. Especially is this the case with epileptics, although, doubtless, as Dr. Clouston says in his case already quoted, the medical evidence would be ridiculed and the physician accused of trying to defeat the ends of justice.

A Case of Schmerz-freude, "Pain-Joy."—Professor Leyden recently presented to his class at Charité a young lady affected with "schmerz-freude," says the Berlin correspondent of the *Therapeutic Gazette*. It is a pity I cannot translate that name for you, for "pain-joy" would convey no meaning to you. The patient, as the professor explained, belonged to that class of hysterical women who not only experienced no pain during an operation, but, on the contrary, had a morbid desire to have otherwise most painful operations performed on them without an anæsthetic. The patient in question had, during a paroxysm of hysteria, fractured her lower jaw and injured the facial artery. The injury proved a most serious one, and necessitated the ligation of the facial and carotid arteries, and, finally, the removal of part of the lower jaw. The patient insisted upon having all three operations performed without an anæsthetic, and told the operator that she had derived great pleasure from the operation.

Clinical Department

SURGICAL TREATMENT OF PUERPERAL PERITONITIS.

By Z. H. EVANS, M.D.,

BAY CITY, MICH.

Professor M. D. Mann, of Buffalo, N. Y., says that there is no reason why pus within the abdomen should not be let out as well as pus within the pleural sac, or within any other serous cavity. Under such circumstances the cavity is simply converted into a huge abscess, and as such should be drained. Nor does it make any difference what the origin of this pus may be. It is all the same whether it comes from the bursting of an abscess of the ovary, or from a gonorrhœal salpingitis, or from a suppurative process originating within the uterus after confinement and extending through the tubes to the peritoneal cavity. The pus, if present, must be evacuated before recovery can take place. Several things stand in the way of the general adoption of the operation. One is the traditional fear of the peritoneum—a fear which still lingers in the minds of the general profession, but which has long since vanished from the thoughts of the laparotomist. If there is already inflammation, with pus formation, what worse can happen? What harm can the opening of the cavity do? Such incision, if made with due care, is in itself absolutely without danger, as has been proven over and over again. So if no good is done, as might happen in the case of a mistaken diagnosis, no harm will result. Dr. Joseph Price, of Philadelphia, the well-known authority upon this subject, informs me that he has operated upon some ten cases with very happy results. He says that in well-marked cases where you find something in the pelvis that you can put your finger upon, and when you are satisfied that there is muddy fluid, pus, and lymph in the abdomen, section, irrigation, and drainage is the treatment paramount.

In proof of the above statement I would call your attention to the following case:

I was called, January 25, 1889, to see Mrs. B——, German, aged thirty-four, mother of four children. Upon my arrival at the house I learned from the husband that one week previous to my visit she had miscarried at three months, at which time flooding took place to the extent of saturating the mattress through and through with blood, all of which was allowed to remain on the bed up to the time of my visit. Owing to the stifling stench it was impossible at that time to make any examination. I therefore ordered the bedding to be changed, patient sponged off, and the vagina irrigated with a weak solution of carbolic acid, promising to call again later in the day. At my next visit I found the sanitary condition of my patient somewhat improved, although the stench was lingering still. I then proceeded to the examination of the patient by first taking the temperature, which was found to be subnormal; pulse, 157; respirations, 34; tongue presented a dark, dry fur down the centre, while the abdomen was distended to a marked degree, and the entire body bathed in a cold clammy perspiration. In truth I believed the patient to be in *articulo mortis*. The case being of such a nature I was desirous of the counsel of my friends Dr. E. G. Miner and Dr. John L. Elliot, and requested that they be sent for at once. Upon their arrival they gave the patient a very critical examination, and gave it as their opinion that the patient had but a few hours to live (which opinion was thoroughly in accordance with my own). After communicating to the husband and friends the views of the physicians, he then inquired if there was nothing further to be done to save the life of his wife. I replied by saying the only alternative left was to open the abdomen and wash it out. He at once acknowledged his willingness to permit the operation, and requested that it should be done at once. After a brief consultation with the physicians present we decided

first to try and stimulate the patient. I therefore ordered whiskey, milk, carbonate of ammonia, and tr. digitalis to be injected every three hours during the night into the rectum. On calling the next morning, much to my surprise, I found the patient still alive, and she expressed herself as feeling quite free from pain, which fact led the friends to indulge in the false hope that she was better. This condition of things convinced me at once that it was but one of the early preludes to an approaching death, and so expressed myself to all concerned. In spite of the unfavorable condition, however, I at once made ready for the operation. When the patient was slightly under the influence of chloroform, she was placed on a table opposite a good light, and the abdomen opened as speedily as possible. This accomplished, she was now turned over upon her face and a quart or more of serum allowed to drain away, at the same time I placed my hand over the wound in the abdomen in such a way as to prevent the intestines from protruding. When the serum had all drained out, the patient was turned back upon the table, when, with the aid of a Davidson syringe, the cavity of the abdomen was flooded with plain warm water, and again the patient turned upon her face as before, and the water allowed to come away. The second time it came away clear and free from any tinge or color. A large sized soft rubber drainage-tube was now inserted and carried to the lower portion of the pelvic cavity. Four deep sutures were then passed, and a compress of cotton and flannel binder applied. This constituted the entire dressing. The patient was now placed in bed, more dead than alive, surrounded by dry heat, and by free use of brandy she, after a few hours, recovered from the shock of the operation. On calling the next morning I was delighted to learn that she had during the night taking nearly a quart of milk and retained it, something she had not been able to do for some days previous to the operation. I found the pulse 112; temperature, 101½° F.; respirations, 20, and the entire body warm. She remained in about this condition until the evening of the third day, when she was seized with a violent chill, which lasted for nearly an hour. I was at once sent for, and on arriving at the house found my patient delirious; temperature, 105½° F.; respirations, 33; pulse, 157. I at once removed the drainage-tube, and on examination found the lower end plugged up with thick pus. This condition of the tube, together with the low condition of the patient, convinced me that I had pus within the abdomen to deal with. Consequently I reopened the wound and again flooded the cavity with warm water, afterward closing the wound with adhesive plaster. There came away at this time at least one pint of thick, creamy pus. The intestines were everywhere matted together, and had to be separated with my fingers. I again ordered the injection of whiskey and milk to be given every three hours during the night. Calling again early the next morning, I learned that the patient had slept quite well during the night. Pulse, 105; temperature, 101½° F.; respirations, 20; skin moist and the entire body warm. From this on she gradually improved, and at the expiration of five weeks from the time of the operation she had so far recovered as to be able to assume the cares and duties of her household.

A CASE OF PNEUMONIA.

By O. H. MERRILL, M.D.,

CORINNA, ME.

G. W. N——, male, aged forty-one, a member of a highly neurotic family, had always been well with the exception of slight rheumatism. On January 3, 1890, he had a severe chill followed by all the other usual symptoms of pneumonia. It was limited to the inferior lobe of the right lung. The disease pursued an ordinary course, and terminated by crisis on the fifth day.

Pulse, temperature, and respiration became nearly normal and remained so for two days. January 10th there was, however, a sudden change for the worse, and on examination it was found that the pneumonic process had invaded the middle lobe of the same lung. The severity of the symptoms steadily increased for the next seven days, till on January 17th the condition of the patient was as follows: pulse, 140; temperature, 105°; respirations, 54; tongue very dry, and uncontrollable delirium. Antipyretics, hypnotics, and stimulants, in as large doses as seemed safe, did not materially improve his condition; in fact they produced very little effect of any kind. January 18th his condition was the same, except that the raging madness had given place to moderate stupor, which continued for the next two weeks. At that time subsultus tendinum and carphology were prominent symptoms. He also passed his urine and fæces into the bed and swallowed with difficulty. It was supposed that death would shortly occur. Nevertheless, by the very free use of hypodermic injections of digitalis, caffein, and brandy the action of the heart was somewhat improved, and by January 19th the pulse was 130, temperature 104° F., and respiration 40. No perceptible change occurred for the next three days, except that on each night, about twelve o'clock, he would appear worse and seem about to die. This condition was combated on each occasion by the rather free administration of brandy. January 23d his pulse fell to 125, and his temperature to 103° F. From that date the pulse-rate decreased from one to five beats per day, and the temperature about half a degree in the same time, till on February 5th the pulse was 96, temperature and respiration normal. The violence of the symptoms, the extreme depression, which was maintained for many days during which life hung by the merest thread, the pro longed course of the disease, and the method of recovery, serve to give interest to the case.

A CASE OF PLACENTA PRÆVIA CENTRALIS.

By FRANK WARNER, M.D.,

COLUMBUS, O.

On November 30, 1888, I was summoned to see a woman, who was eight and one-half months pregnant, for the relief of a violent hemorrhage which had begun a short time before. The diagnosis rested between accidental hemorrhage and placenta prævia. Examination revealed a thick, boggy mass occupying a part of the cervical canal, and from the os a large quantity of blood was pouring forth. The hemorrhage was controlled by a tampon. The following morning I removed the tampon; and again making an examination found the placenta extending almost to the os externum. On inquiry, I learned that there had been frequent slight hemorrhages for six weeks previous. The patient was quite anæmic and feeble, with a weakened pulse. To allow this condition to continue longer meant more hemorrhages, and that too from a patient who could ill afford to lose more blood, and it was decided to bring on labor.

The cervix was dilatable, and my plan was to introduce a Barnes dilator and, after a sufficient opening was secured, to tear away the placenta and turn.

In this I was overruled by my *confrères*, who thought the better plan was to bring on labor by rupture of the bag of waters, afterward tamponing the vagina to restrain hemorrhage while the cervix was dilating, and to trust to the head coming down to stop the rush of blood.

This proposition was acceded to, and the bag of waters ruptured. After a very considerable amount of water had drained away, tamponing was resorted to, for hemorrhage had again set in. In one hour labor pains began. The tampon was left in for five hours. The labor pains had now become quite powerful, and in examining the tampon, I found that during each pain it was firmly pressed down upon the perinæum, but no blood escaped.

The tampon was removed to see what progress had been made. A pain came on, and as soon as the pain was over severe hemorrhage took place. The cervix

was found dilated sufficient to admit of the introduction of a hand. Occupying the dilated cervix was found, not the head of the fœtus, but one mass of bleeding placenta.

It was now plain that a change of tactics was urgently demanded; so, placing my patient under the influence of chloroform, I introduced my right hand into the vagina and tore away all that part of the placenta occupying the left side of the cervix and body of the uterus, quickly introduced the hand into the uterus, found a foot and brought it down, aiding the turning process by manipulation of the left hand over the abdomen. This turning process completed, the hemorrhage ceased. The delivery of the fœtus now occupied about half an hour.

After the child's birth it was found to be a female, well developed and well nourished, but it was quite feeble. The mother and child were left that afternoon doing well, but in the course of the night a severe post-partum hemorrhage set in which came near ending the woman's life. I was summoned at once, and succeeded in stopping the hemorrhage by kneading the uterus and the use of hot-water vaginal injections, together with additional doses of ergot, for she had already taken several doses during the course of the evening, in anticipation of this hemorrhage, which is such a frequent sequel of placenta praevia. From this date on, nothing of special importance developed; convalescence was tedious, the patient remaining in bed four weeks, but finally both mother and child made a perfect recovery.

POISONING WITH ANTIPYRINE.

By E. W. YOUNG, M.D.,
NEW SHARON, ME.

G. D——, aged forty-three, male, three weeks convalescent from neuralgia of the bowels, came into my office, complaining of a slight attack of sick headache. I administered at nine A.M. about six grains of antipyrine, dissolved in water, with one fluid drachm of whiskey. In three minutes after taking the mixture the patient spoke of a peculiar sensation upon each side of the fauces. In ten minutes he left my office to go to his business. Unpleasant symptoms, such as a tumor-like sensation over the notch of the sternum, accompanied with slight dyspnœa, occurring soon after leaving me, he returned after being absent from the office fifteen or twenty minutes, considerably alarmed and with appearance of much suffering. He complained of severe pains in the shoulders, extending up along the side of the neck and down the arms, in the groins, extending down the inner surface of the thighs, and in the mediastinal region. He was also troubled with vertigo, dimness of vision, and nausea, though he did not vomit. Concluding that the whole quantity taken had been at once absorbed into the circulation, I immediately began the use of cardiac stimulants and anodynes, through the stomach. The pulse was increased in frequency and somewhat weak, though regular in rhythm, the highest rate being reached after one hour, 108 per minute, and continuing such for two or three hours.

Within fifteen minutes after returning to me the pain became less severe, when he then began to itch intensely, first over the region of the back but soon spreading to all parts of the body, and after a very short time an eruption, identical with that of urticaria, covered nearly the whole surface, continuing more or less severe for three hours, then subsiding entirely. The pain last to be dispelled was that in the neighborhood of the stomach and mediastinal region. Toward 4 P.M. the patient expressed himself as feeling "all right" again and so continued.

I think it worth while to record these cases, in order to determine for or against the use of this remedy. The most significant point in this case is the smallness of the dose administered to a robust adult, as compared with the average dose. The severe pains are a feature of the case, also, that I have never seen mentioned in any of the reported cases that have come to my knowledge.

FATAL PODOPHYLLIN POISONING.

By W. H. DUDLEY, M.D.,
NEWPORT, N. Y.

I was called to see Mrs. O——, aged sixty, at 1 A.M., September 11, 1889, and found her in the following condition: Face, feet, and hands quite cool; cold perspiration standing on face; pulse, 60, quite weak and thready; respirations sighing, and speaks with difficulty. Says she took some mandrake the evening before, and soon afterward (about 10 P.M.) commenced vomiting and purging which continued to the present. Both vomited matter and stools contained bile. Two hours later the vomiting and purging had ceased, the pulse rose to 70 per minute, the hands and feet getting warm, respirations were natural, and the patient expressed herself as being comparatively comfortable. About seven o'clock in the morning the patient felt so far recovered that she arose and dressed, but soon lay down, feeling quite depressed. Her mind now showed aberration, and memory of past events defective. Seen at 3 P.M.: Primary symptoms of depression returned, but no purging or vomiting.

At 9 P.M. of the same day (about twenty-four hours after taking the podophyllin) the patient was comatose; pulse, 100 to the minute, full, soft, and compressible; temperature, 100+° F.; pupils slightly contracted; respiration, 38. The hand applied to the surface would suggest a higher temperature than is shown by the thermometer.

From this time till 4 A.M. of the morning of the 14th there was a gradual decline. Occasionally she would arouse sufficiently to take food and remedies, but was for the most part comatose. The urine had to be drawn, and was found to be smoky in color; specific gravity, 1.020, acid; albumin one-eighth volume after standing; microscope showed large quantities of blood-cells, but no casts were discovered. In this case there was an error in the patient's dose. She supposed she was taking mandrake, while she took its resinoid, podophyllin. The quantity taken, as shown by the patient before her mind became clouded, was found to weigh about five grains. In this case the treatment consisted of, at first, morphia, one-eighth grain, followed by small quantities of whiskey; later, of food and stimulants, as it was possible to exhibit them.

The primary symptoms of poisoning were removed rather promptly when the condition of the patient promised recovery, but those developing later showed an unrecorded secondary action which would suggest that the liver had been stimulated to the production of a large amount of cholic, choleic, taurocholic, or glycocholic acid, the effect of which was to bring about a condition similar to that of cholæmia, minus the jaundice, a symptom absent throughout the duration of the illness—about eighty hours. No post-mortem was obtained. It should be stated that the husband of the patient took a similar dose of the same drug, and suffered primarily in about the same manner as his wife, though in a minor degree, which was followed by a depressed condition for two or three weeks, but finally recovered, and has since enjoyed his usual health.

PIGMENTATION OF THE SKIN AFTER THE INTERNAL USE OF ARSENIC.

By L. WEHLAU, M.D.,
SCRANTON, PA.

In the *Allgemeine medizinische Centralzeitung*, Berlin, September 11, 1889, there are reports of two cases of pigmentation of the skin after the use of arsenic, published by Dr. E. Haffner, in connection with a similar case presented by Dr. William Leszynsky at the Academy of Medicine, New York, April, 1889. In view of the scarcity of similar cases, I may be pardoned for relating the following one, which has additional interest from the fact that pigmentation took place in a very short time, and after very small doses of arsenic.

With Dr. Haffner, bronzing of the skin appeared in one case a year and a half after the use of five to eight drops of Fowler's solution three times a day. In the second case, four months after the use of eight drops three times a day.

On April 25, 1889, I was called to see Mrs. M——, nationality German, aged thirty. Married eleven years. Number of children four, the oldest ten, the youngest six years of age. She had always been a very strong and healthy woman up to two years ago. Since then she has suffered from loss of appetite, strength, and weight. I found her in bed on account of her weakness. Examination of the chest and abdomen did not furnish any clue to her condition. In regard to pelvic symptoms, she has suffered for the last two years from leucorrhœa. The formerly normal menses had become very light and scanty. There was some backache. Examination revealed a tear of the perineum, with slight recto- and cystocele, an endocervicitis as the result of laceration, the uterus a little lower down than usual, fundus movable anteriorly; tubes thickened, ovaries prolapsed, no tenderness on pressure.

For the first five weeks Mrs. M—— was treated with iron, quinine, etc., hot douches, local applications to endocervix, and the patient grew worse continually. At this stage Dr. Guenster, who kindly saw her with me, pointed out a slight enlargement of the spleen, and the possibility of leukæmia suggested itself, but the result of a microscopical examination of the blood being negative, we made our diagnosis of anæmia progressiva perniciosa, and prescribed Fowler's solution, five drops three times a day. A few days afterward Mrs. M—— was taken sick with a very severe peri- and para-metritis, resulting in suppuration and perforation into the rectum, and into the vagina fourteen days later. Soon after the discharge of pus, and when her stomach, which had been upset, got into a better condition, I put her on arsenic again, five drops three times a day, and from this time on a wonderful improvement was noticeable. She gained every day, and four weeks after the perforation of the pelvic abscesses, she was able to walk through her garden without help; but after having taken the Fowler's solution for three weeks, the highest dose having been seven drops t.i.d., she developed a discoloration of the skin that reminded one of a far-advanced case of Addison's disease; the pigmentation being most pronounced on the abdomen, thighs, face, and arms.

Having seen Dr. Leszynsky's case at his clinic in Demilt Dispensary, I stopped the Fowler's solution, to resume its use three weeks later in four-drop doses. The greatest intensity of pigmentation lasted about ten days, and then, just as in Dr. Leszynsky's case, with the development of a fine, whitish desquamation, the skin returned to its usual color in about six weeks time, although the Fowler's solution was continued in four-drop doses during the latter part of this period.

Mrs. M—— is at present entirely well. The only thing remaining of her pelvic trouble is a left lateral uterine version, the womb being slightly movable. She experiences no trouble from this condition. I may state in conclusion, that in this case, as in that of Dr. Leszynsky's, the patient was a brunette.

A SUBSTITUTE FOR THE PLASTER DRESSING.

Dr. George C. Brown, of Gainesville, N. Y., writes: "I desire to call the attention of the profession to a permanent dressing, which, so far as I know, is new, and which I have used with benefit in place of the more or less clumsy plaster dressing.

"The mode of construction is as follows: When the injury is between the foot and knee, a well-fitting stocking is the most convenient groundwork. At other positions portions of the underwear may be made to serve a good purpose, the essential point being to have the groundwork fit without wrinkling. To this surface apply grocer's coarse sugar paper, cut in strips of suitable width—from three-quarters to one inch being the most convenient width for the limbs—with a good quality of furniture glue. After the desired thickness has been reached it should be left several hours to harden, when it can be removed the same as the plaster dressing, by slitting from one end to the other, when it can be sprung off. I then apply more strips of paper wherever needed to strengthen the splint, trim out from half an inch to one inch on the cut edges, so as to insure constant apposition in case of reduced swelling. Then cover the whole with a cloth covering similar to the inside, glue it thoroughly to the surface, and bind all raw edges with bandaging muslin. After the glue is thoroughly dry, to make a handsomer finish, I usually apply a coat of carriage paint and varnish, and, finally, fasten a row of shoe lacers on either side of the cut edges for lacing the splint on to the injured part.

"The advantages I have found in this dressing over plaster are: 1, It is lighter and more easily applied; 2, it is more durable, lasting with careful use from one to two years; 3, it is readily removed and re-applied; 4, it is cheaper, and can be applied anywhere plaster can, and may be substituted for the leather jacket, which is usually too expensive for poor patients to purchase.

"I frequently render it porous by punching holes through the splint at intervals of an inch or two, making it more comfortable during hot weather."

Progress of Medical Science.

The Immediate and Remote Results of Operations for Local Tuberculosis.—M. Léon Petit has summarized the facts brought out by a recent discussion on this topic. Surgical tubercular lesions—caries of bone, articular fungosities, scrofulous adenitis, spina ventosa, cutaneous ulcerations, etc.—are due to the presence of tubercular elements, and contain the bacillus of Koch. For some time—and in particular since the nature of the tubercular lesion has been known—there has been a constant strife between operative medicine and therapeutical medicine as to the treatment of the local lesions. To solve the question we want facts, and not reasoning. We must classify the facts collected into numerous divisions, and we must follow the cases for a number of years. It is only thus we can appreciate the immediate and remote effects of operation. The difficulty arises in our being often unable to follow the after-history, as the patients are lost sight of. The immediate results may be good, mediocre, null, or bad. It has been said that with antiseptic dressing there are no complications with operations on the tuberculous; that numerous facts testify that the operation may give start to lesions and to tubercular lesions, in organs remote from the operative zone—lungs, meninges, liver, kidneys—and provoke the rapid development of these lesions. Many cases of syncope—mortal or not—met with during or after anæsthesia, are due to the existence of miliary tubercle of the lungs, which is often impossible to discover by auscultation, and only reveals itself by *post-mortem*. Mollière, of Lyons, advises, when there is phthisis in the third degree, rapid operation, in order that the quantity of ether or chloroform may be reduced to a minimum. The traumatic accidents consecutive to operations on the tuberculous depend most frequently on infection produced by the presence of common pyogenic microbes in the wounds of these subjects. In other words, according to Mollière, the results of operations on the tuberculosis may be benign, provided we can avoid traumatic fever. The remote results may be good, mediocre, or bad; good, when to operative success is added therapeutical success; mediocre, when there is operative success, but the tuberculosis after a time again appears, ending in death; bad, when there is neither operative success nor therapeutical success.

In the classification proposed by M. Verneuil, we must

take account of the circumstances which depend on the operation; the lesions of the patient and his environment. The operative results would be different, according to the general treatment followed by the patient during and after operation, and will depend upon whether a cutting instrument, cautery, or injections be used; complete or incomplete extirpations have also their effect. The results, according to Boeckel, Verneuil, and Ollier, are better in acquired than hereditary tuberculosis. M. Jules Boeckel (Strasburg) states that out of 204 cases of amputations and resections performed for local tuberculosis, the mortality of the amputations has been double that of the resections. The results differ again, according to the seat and extent of the lesions. The region invaded is of no great importance. The gravity of the operation, too, is different, according as the tuberculosis has its seat in the pleura, peritoneum, or finger, in the hand or foot, in the ganglions or the bones. Resections of the neck give excellent results, because the patients are not obliged to remain in hospital. Two or three days after operation—thanks to antisepsis and immobilization—they may be sent out to the pure air. The results are inferior in the case of the foot, because the patients are obliged to remain in bed for many months. They live in a bacillary atmosphere, and if not already infected they become so, according to Ollier, by absorbing the bacilli in the air they respire and by the food they take. In tuberculosis of the ganglions, generalization may be rapid after extirpation by exciting the neighboring ones, which often appear healthy because they are small, but microscopical examination often proves that they contain bacillary nuclei. Ablation of the ganglions is then a bad operation, which should be interstitial injections of anti-bacillary solutions. In articular tuberculosis resection only allows complete ablation of the lesions. The immediate results are yet more favorable than in extirpation of the ganglia. But amputation is preferable to resection. Operations on the bones give better results still. In certain osteo-arthrites, the bones are diseased through the whole extent of the marrow. There are tubercular nuclei, without appreciable symptom, on the side of the periosteum, or of the soft parts. Previous trephining of the bone will establish the diagnosis. Partial amputations leave interminable fistulæ, and when these lesions are in certain situations, as the knee, exarticulation of the hip is preferable. In osseous tuberculosis we must distinguish two forms—the one circumscribed, the other invading. The first may be cured by local action; the second yields to amputation of the member when the means employed to arrest its march have failed. In infancy, intra-articular cauterization gives the best results. In the adult, thirty to forty years of age, resection is indicated; but when the lesions are extensive, and we cannot remove all by resection, Ollier counsels amputation Leconte lays down that in tuberculosis of the limbs, radical operations are preferable to sparing ones. In tuberculosis of the bladder, when palliative treatment by intra-vesical injection and internal medicine are powerless, we must act direct upon the lesion. Practise hypogastric section, and by raclage remove the diseased part of the mucus. In four cases Professor Guyon has obtained temporary recovery, with relief of suffering. Guyon and Le Dentu recommend permanent drainage, and prefer the hypogastric operation to the perineal one. At the end of a certain time the drainage-tubes can be replaced by a special apparatus adapted for hypogastric fistula. The results obtained by the operation for tuberculosis of the bladder depend above all on the state of the kidneys and the prostate. The kidneys are always attacked before the prostate, and the operation can only be put off by palliative treatment. Tuberculosis of the kidney may be cured by the total extirpation of that organ; that of the prostate by curage; that of the eye by total ablation; that of the uterus by raclage and cauterization; that of the ovaries and the tubes by a radical operation. Operative interference, then, in local tuberculosis gives excellent results, as it removes the causes of infection, and prevents other parts of the body from being infected.

Adults require a little more radical operation than children. The statistics of children cannot be applied to adults. In the infant we can cure almost all tuberculous affections without having recourse to the bistoury. M. Leconte goes much further, for he thinks even in adults we may obtain the cure of local tuberculosis by general treatment and interstitial injections. In subjects attacked with pulmonary phthisis, with local tuberculosis, the radical ablation of the latter may be followed by immediate reunion, as in healthy subjects, and by considerable amelioration of the pulmonary lesions.

In conclusion, thanks to antiseptic treatment, operations on the tuberculous are indicated in every case of local lesion, and the results must not be calculated from the pre-antiseptic day, as recent results are much more encouraging.—*The Provincial Medical Journal.*

The Use of Strophanthus in Children.—Demme, having conducted a pharmacological investigation of tincture of strophanthus, and arrived at the same conclusions as other authors (Langaard, Blumenau, etc.), has carefully studied the employment of the preparation in children. Twenty-one cases are recorded, namely, seven of mitral disease without compensation, five of scarlatinal nephritis, three of pleurisy with exudation, and two each of bronchial asthma, tuberculous phthisis, and pertussis. Briefly, Demme came to the following conclusions: 1. Strophanthus is useful in childhood, but can only be administered from the fifth year onward. Dyspeptic troubles are only met with exceptionally. Larger doses than three drops four or five times a day are to be avoided. 2. The principal action is to increase the urinary secretion, brought about through the increase of blood-pressure. Compensation of valvular incompetence becomes more assured than is ever the case with digitalis. Where the blood-pressure is normal or already raised, the action of strophanthus remains in abeyance. 3. The second effect of strophauthus is the removal of dyspnœa, especially in cases of nephritis running a chronic course, bronchial asthma, and pertussis. Here also increase of blood-pressure comes probably into play. 4. Where speedy compensation of valvular defect, prompt increase of blood-pressure, with adequate slowing of the pulse-frequency, and increase of the urinary secretion are desired, digitalis is to be preferred to strophanthus, while the latter is indicated where digitalis has lost its effect and in urgent dyspnœa. In such cases Demme recommends a combination of the two remedies. 5. Cumulative action or loss of power on long use Demme failed to observe.—*Centralblatt für klinische Medizin.*

A Fatal Case of Unsuspected General Osteomyelitis.—One of the advantages which the hospital physician has over the general practitioner is that he is able to investigate after death the obscure disease-processes which have baffled his comprehension during life. This is especially true of those rare cases in which chronic degeneration of parts difficult to reach occurs without palpable alteration in the form or density of the organs affected. A case in point, which would in private practice have been classed under the title "pernicious anæmia" (one of the little shrouds under which we inter obscure cases), is related by Dr. Knott in the *British Medical Journal*, February 1, 1890. The patient, a well-knit seaman, twenty-four years of age, who had at different times suffered from pleurisy, remittent fever, and purpura, with dyspepsia, but who had enjoyed fair health for the last three years, complained of slight, ill-defined pains about the chest, epigastrium, and loins, saying that he had been ailing for three weeks, and had lost flesh and strength. Upon careful examination nothing abnormal could be detected in regard to temperature, appetite, tongue, bodily functions, etc.—the urine being only slightly phosphatic—but as he looked anxious and ill, he was put to bed and

dieted. Next day there was tenderness in epigastrium and hepatic region, without enlargement of liver, and weakness of respiratory murmur on right side. The sternal half of the right clavicle was found to be enlarged, in consequence, apparently, of a fall some years before. The heart-sounds were normal. During the next ten days he began to lose appetite, and to vomit after meals —the vomiting becoming gradually more frequent, with ejection of a bitter liquid of the color of yolk of egg or green. There was no rise in temperature, and no localized tenderness in any of the bones. The patient was removed to hospital, and died forty four days after admission. In hospital he became very weak and thin. There was much tenderness about the chest-walls and some swelling over the sternum for a few days. Epistaxis occurred several times, the bowels became very costive, appetite failed completely. Death set in by exhaustion. The post-mortem examination seemed at first to throw very little light on the nature of the disease which had, during life, sorely puzzled the members of the hospital staff. The body was greatly emaciated; the skin was of a white, waxy color. The organs of the abdomen were very pale and bloodless; all the fat had been absorbed; the liver and kidneys were healthy, as also the pancreas and spleen. The stomach presented the cicatrix of a healed ulcer with a hard, gristly base; the glands along the lesser curvature being enlarged and gristly. The blood-vessels were healthy, but contained only pink serum. The lungs were bloodless but healthy, with old pleuritic adhesions at the right apex. The heart and great vessels were normal, but contained only serum. So far nothing had been found to explain the great anæmia-changes which were everywhere apparent. The case might have remained a mystery had not one of the ribs been accidentally divided at a bony part in the removal of the sternum. Though apparently healthy from without, it was found to be quite soft, its cancellous tissue having broken down and having been replaced by a pink creamy matter. Other ribs were in the same condition, as well as the sternum, the clavicles, and the femora. Dr. Knott thinks that this general chronic osteomyelitis was the initial disease, and that the extreme anæmia was the result of this hidden cause. He suggests that, if this interpretation is correct, it goes to strengthen the theory that the red corpuscles of the blood are formed originally, or in some way matured, in the marrow and cancellous tissue of the bones.

Local and General Manifestations of Infection.—M. Bouchard, at the Académie des Sciences, recently presented a paper on the part played by local injury in infective diseases. The more inclined the organism was, he said, to a general morbid condition, the less there was of local injury. For instance, anthrax produces a malignant pustule in man; but in a rabbit, where the local lesion is perfectly trifling, it produces acute general infection. The relation was analogous to that between fœtal and inoculated small pox, between inherited and acquired syphilis. It might be said that, as a rule, infection by a limited lesion is less serious than infection by the blood. If there is complete systemic infection the local lesion may be completely lost. M. Bouchard, with the help of M. Charrin, had made some inquiries on the method of production of the local injury. Taking the *Bacillus pyocyaneus* as an example, he thought he could show the methods by which the local injury protected the animal from general infection; they were not unlike what M. Metchnikoff had described. The organism had several ways of overpowering the microbe. The liquid constituents of the body might be unfavorable to its growth; if there were much local inflammation about the place of inoculation there would be more diapedesis of leucocytes, and these leucocytes were found to be very destructive of microbes; or lastly, it might be that the microbes during their short life in their limited locality might secrete something that vaccinated the body and helped its resistance to the further spread of the microbe. MM. Charrin and Noges had made some more, particular observations on this last point. They had found the fatal action of the serum of the blood on many microbes. The *Bacillus pyocyaneus* was the one which would most resist this action of the serum. It could grow fairly well in the serum of healthy rabbits, a little in the serum of those that have been vaccinated against the disease, and not at all in those which are having the disease. But still this fatal power of the serum is not sufficient to give full immunity to those which possess it; complete immunity is a resultant of this and other forces.—*The Practitioner.*

Action of Boric Acid on the Kidneys.—Dr. Jacob Plaut has made a number of experiments as to the danger of boric acid when employed as an antiseptic, and has published his results in an inaugural thesis presented to the University of Wurzburg, 1889. These experiments appear to show that the constant employment of boric acid, when brought into the peritoneal cavity or under the skin, results in many cases in rapid death if the quantities dissolved are large, or, if small, the final fatal effect is preceded by acute parenchymatous nephritis. The author does not seem to have established that the death of the various animals poisoned by boric acid was attributable to the renal inflammation, but his experiments are sufficient to show that boric acid is by no means the safe antiseptic which it was supposed to be.—*The Therapeutic Gazette.*

Succinate of Iron in Gall-Stones.—Succinate of iron is an amorphous reddish-brown powder, insoluble in water and alcohol. According to Dr. Buckler, in combination with chloroform it is very efficacious in gall-stones. The chloroform is given in ten-drop doses from four to six times a day, and the succinate of iron in teaspoonful doses after each meal. Its use is to be continued for months, until complete solution of the stones takes place and the tendency to their formation is overcome.—*Medical Press.*

Treatment of Puerperal Eclampsia.—Voit's article on this subject in *Volkmann's Sammlung Kl. Vork*, 304, is likely to exercise a good deal of influence on the treatment of this affection in Germany. He strongly recommends narcotism by means of opium or morphia as the sheet-anchor, or chloral hydrate may be employed, but it possesses no advantages over the first named. The first thing is to give a dose of 0.03 to 0.04 gramme of morphia, and then smaller doses to keep up deep narcosis. It is an advantage to narcotize a patient quickly, and then chloroform may be given first and morphia afterward. Diaphoresis is a valuable means, which may be protracted by warm baths and enveloping in moist, hot clothes, without any fear of hemorrhage. The narcosis is not interfered with by these, and hypersecretion of the respiratory tract is not to be feared, as after the administration of pilocarpine. The best practitioners have a decided aversion for pilocarpine nowadays. The labor must also be expedited as much as possible. If the os utero is closed, the membranes may be ruptured or a bougie introduced. He mentions the procedure recommended by Moudot under these circumstances. This gentleman ruptures the membranes by passing a flat, metallic cannula through the cervix, and allows about ten litres of a one per cent. carbolic solution to flow into the uterine cavity under gentle pressure.—*Medical Press.*

"How Do You Do To-day?"—A physician, illustrating the evil custom of talking to an invalid about his pains, says that once he requested a mother to mark a stroke upon a paper each time that she asked a sick daughter how she was. The next day, to her astonishment, she made one hundred and nine strokes. A three months' visit away from home was prescribed.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, April 12, 1890.

THE NATIONAL CONTROL OF OUR QUARANTINE.

THE passage of the National Contagious Diseases bill by Congress marks an era in sanitary legislation which deserves to be noticed. It will be found that this new law may confer extraordinary powers upon the Treasury Department and Marine Hospital Service, powers which Congress has always, heretofore, refused to bestow. In 1796 an attempt was made to enact very much such a law as the present one, but the bill was modified, and finally defeated. Up to 1878 the National Government contented itself with simply aiding the States through its revenue and military officers. Then began the fight of the United States Marine Hospital Service to establish itself as the National Central Bureau for controlling quarantine matters. Its efforts were defeated for a time, and from 1879 to 1883 the National Board of Health exercised very considerable advisory and some executive power over quarantine matters. From various causes, prominent among them being the hostility and ambition of the Marine Hospital Bureau, the National Board failed to secure the confidence and support of Congress, and it lapsed into helplessness from the want of an appropriation. Meanwhile the Marine Hospital Bureau secured the enactment of a law placing an epidemic fund at the disposal of the President in case of need, and providing for its disbursement through the officers of the Marine Hospital Service.

Now comes the law giving to the National Government power to control interstate quarantine, and placing the execution of the law in the hands of the Marine Hospital Service. This service has now gained the two great objects of its ambition, its officers are appointed by the President and confirmed by the Senate, and it is master of the sanitary affairs of the United States. The growth into these proportions of a little bureau in the Treasury Department, intended originally to take care of the sick and disburse the sick-dues of our merchant marine, is a highly interesting thing to contemplate. We trust that it will prove itself worthy of the task imposed upon it; and we are wondering if, when the people find out the new powers which our National Government has assumed, it will continue to allow them. For our part, we believe that it is decidedly the most efficient way to administer quarantine. The doctrine of States rights has often been the shibboleth of unreasoning opposition to sound sanitary legislation, and there has undoubtedly been an immense loss of life and property in the past hundred years on account of the hyperæsthesia of States rights politicians.

A SUBJECTIVE SENSATION OF THE MOUTH IN WOMEN.

THE young practitioner, especially if he is of a scientific turn of mind and has spent much time as a resident in a hospital, is apt to feel a profound contempt for the abnormal nervous feelings which figure so largely in the complainings of his female patients. If he is to be a successful physician, however, he must early learn that these sensations are not to be despised nor disregarded, and must prepare himself for giving patient attention to the tedious accounts of ever varying "aches" and "feelings" poured into his wearied ears, arming himself with a multitude of pharmaceutical missiles of reputed utility. Fortunately for him his success depends not so much on the treatment of each individual symptom as it arises, as on the bracing up of the whole system, and especially the thorough evacuation and cleansing of the digestive canal.

In a few isolated cases a localized disorder of sensation persists in spite of all treatment, indicating probably an anatomical lesion of certain nerve centres in the brain or spinal cord.

In the *Lancet*, January 25, 1890, Dr. Hadden reports four such cases, in all of which there was a sensation of intense, unbearable burning of the tongue, which extended sometimes to the lips and roof of the mouth.

The first patient, a lady of seventy-four years, suffered from aortic regurgitation with irregularity of the heart and dyspnœa. This serious affection was, however, as nothing compared with the misery which she experienced from an almost constant burning and scalding sensation about the tip of the tongue and lips, which made her life almost intolerable and interfered seriously with sleep. No local disorder of the parts could be seen. She was nervous and excitable, and flushed frequently without apparent cause. Cocaine tablets of one-sixth of a grain, and afterward of one-third of a grain, gave her a little relief. Belladonna, ten minims of the tincture, t.i.d., was without influence. The sensations persisted with but little change until her death a few months later.

The second patient, seen but once, was a married woman, aged thirty-five, who had a small epulis. Her sensations were similar to those of the first patient.

The third patient, a married lady of seventy five years, who had been reduced to poverty, had passed the menopause without trouble, and gave a family history free from nervous disorders. She herself, however, had for many years suffered from nettlerash with nocturnal itching; and she was emotional and nervous, blushing readily. Twelve years before she began to suffer from a burning sensation in the middle of the dorsum of the tongue, which had since increased in intensity, involving during the last five years the gums and roof of the mouth. Since its first appearance it had never left her for an hour. After the gums became involved the teeth turned black and decayed. The mouth was of normal temperature. The tongue was clean, moist, slightly fissured, with prominent papillæ. There were some papilla-like outgrowths on the gums. When touched with the finger, the

tongue and gums seemed to burn. There was a constant bitter taste in the mouth. She could detect sugar and salts, but meats tasted bitter. The burning sensation in the mouth prevented sound sleep, day or night, and had been, of late years, so much increased by solid food that she limited herself to liquid diet.

She was still, after six months, under treatment; many remedies, local and general, such as glycerine of borax, boro-glycerine, antipyrin, jaborandi, bromide and iodide of potassium, belladonna, and chlorate of potash, having been tried without avail. The discomfort during the night was somewhat lessened by constant sipping of milk-and-water.

The fourth patient was a florid, excitable married woman of fifty-three, with no family history of neurosis. After passing the menopause at forty-five she began to suffer with flushing of the face, which still persisted. During the past year the tip of the tongue began to tingle. After a sudden mental shock this tingling gave way to a burning in the tongue and mouth, appearing at first at bed-time, but subsequently becoming constant. It was relieved by food and by water and cooling drinks. The taste of sugar and salt could be discerned, but meats were insipid. She slept badly. The mouth was normal in appearance and temperature, and sensation to the touch was natural. All of the teeth had been extracted in the hope of relieving the trouble. No treatment had been of any use, but Dr. Hadden intended soon to try the electric current.

A REVIEW OF THE LITERATURE OF INFLUENZA.

A REVIEWER in Schmidt's *Jahrbücher* has collected a list of sixty-one publications made upon the subject of influenza since the epidemic appeared last October. These communications include studies of the disease in all its phases. Six are devoted to its epidemiology, and discuss its origin and history. Clemon thinks the disease began in Siberia, appearing at Tomsk October 15, 1889; but Heyfelder asserts that it existed in Russia in the summer of 1889. In the early part of December it appeared in Berlin, Paris, and Austria, and in the latter part of December in London and New York. It reached Italy, Greece, and North Africa about the same time, or a little later.

Some twenty communications are devoted to the symptomatology of the influenza, four to its appearance in animals, and ten to the complications of the disease.

Thirteen writers discuss the bacteriology of influenza, but the reviewer has evidently overlooked American studies on this subject. Our readers are already familiar with the results of this work through the contributions of Prudden and others in our columns.

The subject of prophylaxis and therapy has not seemed an attractive one, for we find only five articles upon it. These are devoted to showing that quinine is prophylactic, and calomel more or less abortive or curative in its action.

COSMETICS FOR THE PHYSICIAN.

THE secrets of the toilet, the arts by which lovely woman hides incipient corrugations, effaces blemishes, and softens and beautifies her cutaneous apparatus and its appendages generally, are rarely investigated by the physician. He contents himself with removing some particularly obtrusive mark, pulling out superfluous hairs, or trying, with spirits and Spanish flies, to fasten in the too deciduous hair. Dr. H. Paschkis, of Vienna, however, has attempted to inaugurate a new era in this line, and has written a book, "Kosmetik für Aertze," which is intended to enable the physician to add to the æsthetic enjoyment, as well as physical welfare of humanity. Paschkis's book is said by a reviewer in the *Deutsche Medizinal Zeitung* to be a thoroughly scientific one. Its formulæ are based upon dermatological knowledge and pharmaceutical experience. As illustrations we are given four formulæ for that popular domestic article "cold cream."

One of them is as follows:

℞. Lanolin 10.0
Boracis 1.0
Aqua rosmarin 100.0
M. Sig.: Lanolin-milk

A formula for seborrhœa is the following:

℞. Kali carbonat 10.0
Aqua destillat 100.0
Olei æth. cinamom ..... gtt. 2.0
Olei æth. rosmarin ..... gt. 1.0
M.

For warts our scientific book of beauty prescribes:

℞. Acid. salicylicum 5.0
Collodii 20.0
M.

For sweating feet, five to ten per cent. solutions of chromic acid are recommended.

For dandruff and baldness there are, of course, numerous prescriptions; but, we regret to say, no specific is announced. For a simple wash, as preventive of dandruff, we find:

℞ Kali carbonat 2.00
Aquæ 100.00

The formula for Hebra's dandruff water is also given, viz.:

℞. Spts. æther 100.0
Tinct. benzoin 15.0
M.

Mouth-washes and tooth-powders are given, the author warning his readers especially against the use of salicylic acid for these purposes.

We have not space to describe the merits of Dr. Paschkis's work in further detail. But it is evident that, equipped therewith, the physician can enter on even terms the contest against the balms of Récamier, the secret washes of Lola Montez, and the roborant lotions of the Sutherland and other sisters.

TUBERCULOSIS AND MILK.

A BOSTON gentleman, Mr. Francis Blake, has created quite a stir by his account of the discovery of tuberculosis in the herd of cows which he owned, and which he had believed to be particularly healthy animals. Out of ten cows, six were found to be tuberculous, and were killed. Milk from the tuberculous cows was tested bacteriologically, and found to be free from bacilli. The conclusion reached was that the bacteriological test of milk was not a sure one. This is very true; it is well known that tuberculous cows do not always have bacilli in their milk, and that the milk of such cows may, and as a rule is, perfectly harmless. Occasionally, however,

bacilli appear in it; and still more rarely, these bacilli infect those who drink it. The milk of tuberculous cows is not a virulent poison, it may even be a fairly healthful food; but it always is a possible source of danger, and upon this ground measures to stamp out bovine tuberculosis, and to sterilize milk before it is stamped out, are to be recommended.

ARE MUTILATIONS INHERITED?

The Lancet, in a recent issue, discusses this question and refers to some recent studies by Professor Weismann on the subject. The distinguished professor cut off the tails of nine hundred and one white mice of successive generations, but in no case was a white mouse born without a full-sized 10.5 mm. tail. It has always been something of a puzzle that the Jews should, after thousands of years of circumcision, still bear male infants with long prepuces. Darwin refers to the fact, as noted by Godron, that different races of man have from time immemorial knocked out their upper incisors, cut off joints of their fingers, made holes of immense size through the lobes of their ears or through their nostrils, tattooed themselves, made deep gashes in various parts of their bodies, and yet that there is no reason to suppose that these mutilations have ever been inherited.

It must be conceded that, in the higher mammals at least, mutilations are rarely, if ever, transmitted.

News of the Week.

Not the Best Way to Collect Fees.—A physician practising in Carlisle, Pa., has been arrested there on a charge of having violated the United States postal laws. About March 1st, a man in New Haven received a letter on which appeared the words: "Dead Beat Agency, Carlisle, Pa." It contained a notification that the recipient owed the doctor $36.20. The letter was given to the postmaster, and by him referred to the authorities at Washington, who ordered the too urgent creditor's arrest.

The Louisiana State Board of Health.—Drs. Henry Bezou and S. R. Olliphant, and Messrs. Charles Holloway and Thomas A. Clayton, have been appointed by Governor Nicholls members of the Louisiana Board of Health.

The Quincy (Mass.) City Hospital.—Mr. William B. Rice, a Boston merchant residing in Quincy, has just presented a hospital to the latter city. According to the provisions of the bequest, the medical board is to be composed of three regular physicians and one member of the Massachusetts Homœopathic Medical Society.

An Office Thief with a Big Business.—A woman who made a specialty of plundering physicians' offices was recently arrested in Brooklyn. So many pawn-tickets were found in her possession, all representing the fruit of her stealings, that it was necessary to hire a large express wagon to gather up the redeemed pledges.

Dr. D. Hayes Agnew, of Philadelphia, has been ill, but is now reported to be convalescent.

A Memorial Hospital at Johnstown.—It is proposed to erect a hospital at Johnstown, the cost to be defrayed out of the surplus funds of the flood relief commission. The hospital will stand on a high bluff west of Stony Creek.

Dr. Robert Gibson, of the U. S. Army, stationed at Fort Trumbull, was thrown from his carriage in New London, recently, receiving a severe contusion in the head and breaking two bones of his right arm. The carriage was wrecked.

The Society of the Alumni of Bellevue Hospital.—This society, composed of the attending staff and ex-internes of Bellevue Hospital, celebrated their first annual reunion during the past week with the following programme of the Scientific Meetings: On Tuesday, April 8th, at 8 P.M., at the Mott Memorial Hall, a paper was read on "The Treatment of Simple Fracture of the Patella by Wiring," by Dr. Charles Phelps. It was discussed by Drs. Abbe, Bryant, W. T. Bull, Dennis, Fluhrer, Lange, T. M. Markoe, McBurney, Leale, L. A. Stimson, and Stephen Smith. On Wednesday April 9th, at 11 A.M., a clinic was given at Bellevue Hospital, by Dr. L. A. Sayre. At Mott Memorial Hall, in the afternoon, a paper on the "Ultimate Results of Injuries to the Hip-joint," was read by Dr. Reuben A. Vance, of Cleveland, O. The paper was discussed by Drs. Hartley, L. W. Hubbard, R. H. Sayre, J. McG. Woodbury, and Wyeth. Discussion on "Transient Glycosuria and Delicate Tests for Sugar in the Urine," introduced by Drs. Brandreth Symonds and John Warren; continued by Drs. H. M. Biggs, A. Flint, G. B. Fowler, R. W. Greene, A. Jacobi, E. G. Janeway, W. H. Thomson, and J. W. Roosevelt. On Thursday, April 10th, at 2 P.M., a gynecological clinic was given at Bellevue Hospital by Dr. W. T. Lusk. On Wednesday evening a banquet was given by the society at the Hotel Brunswick. Nearly every one of the one hundred and eighty members was there, while on each side of Dr. Richard Kalish, the President of the society, sat a long line of guests. Dr. Kalish proudly told how the society started off with a surplus of $600 in its treasury. Dr. William H. Draper, in responding to the toast "Old Bellevue," gave many reminiscences of the famous physicians with whom he had labored in the hospital in years past. After Dr. Draper had said a good word for the society, at his request the diners rose and drank a silent toast to the memory of those of Bellevue's physicians who had died in the discharge of their duty since 1847. "The Parson," was the Rev. Dr. R. S. MacArthur's toast, and he accepted the title with a good grace. He had had a good deal to do with doctors, but he was thankful to say that doctors had had very little to do with him. He finished his speech with an appeal for an American university to be established in New York, to be on a plane with the German universities. The other toasts were: "Progressive Medicine," Dr. Alfred L. Loomis; "The Law," Frank Loomis; "Bellevue Hospital in its Relation to Medical Education," Dr. Austin Flint; "The Commissioners of Charities and Correction," President H. H. Porter; "The Patient," Charles B. Alexander; "The Press," Chester S. Lord; "The Trained Nurse," Dr. William M. Polk.

Another University Open to Women.—The University of Basle, the only one in Switzerland which still refused to admit women, has now, in response to an influentially signed petition, thrown open its doors to them.

The West End Medical Society held its third regular meeting on last Saturday evening. This is a new society of the physicians practising on the west side of the Park. Its object is the advancement of medicine and surgery, and the promotion of social intercourse among its members. At the last meeting, Dr. Horner read a paper on "Empyema," and presented a case. The officers of the society are: Dr. W. A. Walker, *President;* Dr. C. B. White, *Vice-President;* and Dr. Richard N. W. K. Horner, *Secretary and Treasurer.* Regular meetings will be held at the members' houses on the first Saturday evening of the month, except during the months of July, August, and September. A paper on some medical or surgical subject will be read at each meeting. The Society has over twenty members.

The Medical Association of Georgia will hold its annual meeting at Brunswick, on Wednesday, Thursday, and Friday, April 16th, 17th, and 18th. According to the published programme, the meeting promises to be a very interesting one. Among the good things promised the members is a clam-bake and oyster-roast on the afternoon of the first day.

The Southwestern Ohio Medical Society.—The semi-annual meeting of this flourishing organization will be held at Springfield, O., on Thursday and Friday, April 17th and 18th.

The South Carolina Medical Association will hold its annual meeting at Laurens, on Wednesday, April 23d.

The Call of the American Committee of the Tenth International Medical Congress.—The Committee of Organization of the Tenth International Medical Congress, R. Virchow, *President;* E. von Bergmann, E. Leyden, W. Waldeyer, *Vice-Presidents;* O. Lassar, *Secretary-General*, have appointed the undersigned members of an American Committee for the purpose of enlisting the sympathy and co-operation of the American profession. We are assured that the medical men of our country will receive a hearty welcome in Berlin. The Congress promises to prove of inestimable value in its educational results, and in securing the ties of international professional brotherhood. It is most important that the American profession should participate both in its labors and its fruits. Delegates of American Medical Societies and Institutions, and individual members of the profession, will be admitted on equal terms. The undersigned, therefore, beg to express their hope that a large number of the distinguished men of our country will appreciate both the honor conferred by this cordial invitation and the opportunity afforded us to fitly represent American medicine. The Congress will be held at Berlin, from the fourth to the ninth of August. The arrangements in regard to a few general meetings and the main scientific work, which is delegated to the sections, are the same as in former sessions. A medico-scientific exhibition, the programme of which was published a few weeks ago, is to form an ingredient part. It is to the latter that the Berlin Committee is very anxious that both the scientific and the secular press should be requested to give the greatest possible publicity. The office of the Secretary-General is Karlstrasse 19, N. W., Berlin, Germany. S. C. Busey, Washington, D. C.; William H. Draper, New York; R. H. Fitz, Boston, Mass.; H. Hun, Albany, N. Y.; A. Jacobi, New York; William T. Lusk, New York; William Osler, Boston, Mass.; William Pepper, Philadelphia, Pa.; J. Peyre Porcher, Charleston, S. C.; J. Stewart, Montreal, Can.

A Mad-House for Royalty.—A London paper states that in the private asylum at Gratz there are now confined Prince Pedro of Saxe-Coburg, Prince Charles of Lichtenstein, and the Duchess of Augustenberg. The Duchess of Alençon was at one time an inmate.

"The Illustrated Medical News," of London, has ceased to appear. A large amount of money was spent in the endeavor to establish it upon a paying basis, but it lived but little over a year.

The Portrait of a Surgeon given to a Church.—The *London Medical Recorder* states that a grateful patient of Professor Billroth's has made a present to a church, in the neighborhood of Vienna, of a portrait of the distinguished surgeon, delineating him as he appears in his operating-room.

Alcoholism and Insanity in Paris.—The number of insane in Paris admitted to the special infirmary for such cases has increased from 3,084 in 1872 to 4,449 in 1888. Alcoholic insanity is said to be twice as frequent as it was fifteen years ago.

The Missouri Medical College of St. Louis has absorbed the St. Louis Post-Graduate School of Medicine. The building and the faculty of the latter institution will be used for the benefit of the senior class and of medical graduates. The Missouri Medical College intends next year to adopt a three years' graded course.

Bequests to Charities.—The Home for Incurables at Fordham gets $5,000 from the will of Thomas Hope, and the same sum from the will of Mary Rogers. The New York Cancer Hospital gets $30,000 from the Rogers estate, and the Hospital for Ruptured and Crippled $20,000. The Manhattan Eye and Ear Hospital and the New York Skin and Cancer Hospital each gets $3,000 from the Hope estate.

International Medical Congress—Special Features.—A special feature of the meeting will be the presentation of literary *souvenirs*. One of these, as we announced some time ago, will be the new edition of Professor Virchow's "Cellularpathologie." Others will be a history of the development of medical societies in Germany, presented by the German Medical Association, and an account of all the institutions established in Prussia for the cultivation of medical science, presented by Dr. von Gossler. The city of Berlin will also contribute a *Festschrift* of a corresponding kind.

Mount Sinai Hospital will soon have a new and commodious dispensary.

International Congress of Women Physicians.—A number of Chicago "lady medicals" have organized a committee for the purpose of securing an International Congress of Women Physicians, in 1892.

The Solicitation of Patients arriving at Hot Springs, by the "drummers" of the quacks there resident, has become such a nuisance that the city council has forbidden the practice by an ordinance, and is arresting the "drummers" and their employers.

A State Sanitary Convention will be held in Norristown, Pa., in May next.

International Medical Congress—Section on Pathology.—In the Pathological Section the subjects already fixed for discussion are: 1, Lesions of the Myocardium; 2, The Part Played by Leucocytes in the Formation of Tissue; 3, Tuberculosis. In the Section of Neurology and Psychiatry a discussion on the Surgery of the Central Nervous System will be introduced by Mr. Victor Horsley; one on Traumatic Neuroses, by Dr. Schultze, of Bonn; and one on the Pathological Anatomy of Dementia Paralytica, by Professor Mendel, of Berlin. In the Section of Hygiene Dr. E. Roux, Director of the Pasteur Institute in Paris, and Professor Löffler, of Greifswald, will introduce a discussion on The Means of Preventing the Spread of Diphtheria; Professors Thiry, of Brussels, and Kaposi, of Vienna, one on The Sanitary and Moral Dangers of Prostitution and the Means of Repressing it; Professors Max Gruber, of Vienna, Erismann, of Moscow, and Dr. Baer, of Berlin, one on Hygiene in Reformatories, Houses of Refuge, Foundling Hospitals, etc.; Professor Sormani, of Pavia, and Dr. G. Cornet, of Berlin, one on International Measures for the Prevention of Tuberculosis; Drs. H. P. Walcot, President of the Massachusetts State Board of Health, von Fodor, of Budapest, and E. Almguist, of Gothenburg, one on The Increased Prevalence of Typhoid Fever in a Number of Districts which had been more or less Free from it for Several Years; Professor Forster, of Amsterdam, one on The Nourishment of the People in Time of War and Epidemic; Professor Franz Hofmann, of Leipzig, and Dr. Petri, of Berlin, one on The Tenability of the Views now Commonly held as to the Injurious Effects of Cemeteries on the Public Health; Professor Flügge, of Breslau, one on Infant Mortality and Infant Feeding. Addresses will also be delivered by Professor Sormani, on The Etiology and Prevention of Tetanus; by Dr. Ludwig Czatary, of Budapest, on The Hygiene of Railway Travelling; and by Professor Neisser, of Breslau, on Venereal Disease and the Medical Control of Prostitutes.

Sections on Rhinology, Laryngology, and Pædiatrics—In the section on Laryngology it is announced that there will be papers on Laryngeal Cancer, by B. Fränkel; Deviation of the Septum, by Moure, of Bordeaux, and Hartmann, of Berlin; Diagnosis and Therapy of Diseases of the Accessory Nasal Cavities, by P. McBride, of Edinburgh, and J. Schech, of Munich; Syphilis of the Upper Air-passages, by L. Schrötter, of Vienna, and Lefferts, of New York; Acute Infectious Inflammations of the Larynx and Pharynx, by P. Messei, of Naples, and Mor. Schmidt, of Frankfort. In the Pædiatric Section Dr. O'Dwyer, of New York, will open a discussion on Intubation.

Regulating Medical Practice in New Jersey.—A law has passed the Legislature creating a State Board of Medical Examiners.

A Slander on American Medical Students.—An English contemporary in the *Medical Press* publishes the following gratuitous slander upon American medical men: "The German schools of medicine continue to have a great attraction for foreign students, nearly two thousand of whom are in attendance. Half of these are Americans, who burn to be able to announce in the local journals on their return that Dr. So-and-so has just located at —— Street on his return from studying under the celebrated X. at Berlin or elsewhere." No such practice as that intimated by our contemporary is current in this country.

Western Pennsylvania Medical College.—The fourth annual Commencement exercises of the Western Pennsylvania Medical College were held in the Grand Opera House, Pittsburg, on March 27th. The degree of M.D. was conferred on twenty-nine graduates.

The Pneumatoscope.—At the meeting of the Vienna Medical Society on February 26th, Dr. Gabritschewski, a Privat Docent, of Moscow, exhibited an instrument invented by himself called a pneumatoscope. It consists of two funnels inverted into each other, and two tubes provided with two end-pieces which the examining physician applies to his ears. The inverted funnel is covered with a light vibrating membrane of india-rubber, and is placed on the patient's mouth so that he breathes into it. According to the inventor his discovery will effect a revolution in thoracic examinations. He has used it very successfully in the diagnosis of chest affections. The sound-waves permit a more accurate differential diagnosis as different breath-tones were produced in the different diseases. The instrument can also be made use of in examining the breast.

Pennyroyal as an Emmenagogue and Abortifacient is much advertised in sporting and other lay journals, and is extensively used by married women in some localities. Dr. A. D. L. Napier writes to the *British Medical Journal* a letter bearing upon the question of limiting its sale by law. He says: "It appears that the therapeutic action of pulegium as an emmenagogue is very imperfectly known. The drug is used very freely by many married women to hurry on delayed periods. One lady told me that she always kept a supply, and took large doses if the menses did not come on. She was much distressed to find that the drug failed to have the desired effect on the occasion I saw her, and added: 'My sister-in-law takes it regularly when she passes her time, and invariably finds the period to come on in three days.' I made some inquiry regarding the practice, and find that among many classes it is recognized as a tolerably certain abortifacient, and esteemed as less hurtful than aloes, savine, cantharides, ergot, elaterium, croton-oil, black hellebore, squills, or even borax. At the same time it is very questionable if any of these drugs can be regarded as absolutely certain to interrupt gestation. Given a healthy embryo in a healthy and normally placed uterus, it is by no means easily injuriously affected. But if by causing irritation or congestion of the uterus an early abortion is once procured, it is very probable that the process may be repeated indefinitely. I cordially agree with the suggestion that greater precautions should be enforced regarding the sale of such drugs."

GOING TO BERLIN.

A NUMBER of our subscribers having written to us for information in relation to the forthcoming congress to be held in Berlin on the 7th of August next, and especially for information concerning the transatlantic voyage and the necessary travel on the other side, we give herewith, with more detail than has heretofore been done at any time, such instructions and advice as may be of assistance to one who has had no experience whatever. The information given as to expenses, and other information of like nature, may be relied upon in every particular.

Preliminary.—Presuming that all who wish to attend the Congress can readily find their way to the city of New York, we may state, beginning from this point, that there are numerous lines of steamers leaving the port of New York for the other side, offering a great variety in accommodation, as well as in the cost of the passage. The fares range from $65, the round trip, on some of the lines, to as much as $600, and even more, for some of the choicest and most desirable staterooms on the newest and most fashionable steamers. It may be stated, however, that whatever price is paid for the ticket, the position and accommodations of every first-class passenger on the steamer, in the saloons, at meals, or on deck, are precisely the same; those paying the highest rates having no advantage whatever over those paying the lowest, except in the matter of sleeping cabins or staterooms.

Passports are not now required, except in Russia and Turkey.

Money.—On arrival in New York you should purchase a letter of credit for such amount as you may have set aside for the purpose, of some first-class bankers, such as Brown Bros. & Co., Drexel, Morgan & Co.

You should also, if you propose landing in England, purchase $10 or $20 worth of English gold and silver, and if you can arrange to do this just before you go aboard the ship, it will be an advantage to you to carry no American money with you. If you land at Havre or Antwerp, get the same amount of French gold and silver, If you land in Hamburg, get the same in German gold and silver. Whatever American money you may have left in your pockets when you go aboard the steamer you can get exchanged into the money of the country that you propose to land in by the purser, although, of course, he will charge you considerably more for the accommodation than a banker would do.

Guide Books.—We think you would find it an advantage also to purchase a good guide book to the countries you intend visiting, before leaving America, as you may have opportunities of consulting it while on the steamer. Baedeker's Guides are considered to be the best. Baedeker's Guide for Great Britain costs $3.00; for Northern Germany, $2.10; for Belgium and Holland, $1.80; for France, $2.10; for Switzerland, $2.40.

These can be ordered through any bookseller before you leave home, or they may be had from Scribner & Welford, 743 Broadway, New York City, who will furnish on application a complete list of these books, or, if preferred, they can be obtained anywhere in Europe.

About Steamers.—Presuming that many physicians will take advantage of their trip across the ocean to see something of other things and places besides the Congress in Berlin, we will give first the list of steamers leaving New York, and their ports of destination, together with the prices charged for the ocean passage alone, and also in connection with railway travel through various points on the other side, to Berlin. Tickets may be procured in New York for the entire round trip, but, except that there is an advantage in saving of expense in purchasing a round-trip ticket by the same line of steamers, we would advise that tickets be not purchased in New York for a fixed route further than to Berlin, leaving the settlement of the return trip for consideration and definite conclusion until after reaching that city.

State Line of Steamers leave New York every Thursday for Liverpool; round-trip tickets from $65 to $95, according to size and location of state-room; duration of voyage, about ten days.

Anchor Line.—Leave every Saturday for Liverpool, or Glasgow; round-trip tickets from $100 to $120 Glasgow service; $120 to $180 Liverpool service, according to size and location of state-room; duration of voyage, about nine days.

Guion Line.—Leave every Tuesday for Liverpool; round-trip tickets from $100 to $180, according to size and location of state room; duration of voyage, about eight days.

Inman Line.—Leave Wednesday and Saturday for Liverpool; round-trip tickets from $110 to $225, according to size and location of state-room; duration of voyage, about seven days.

Cunard Line.—Leave Wednesday and Saturday for Liverpool; round-trip tickets from $120 to $220, according to size and location of state-room; duration of voyage. about seven days.

White Star Line.—Leave every Wednesday for Liverpool; round-trip tickets from $120 to $270, according to size and location of state-room; duration of voyage, about seven days.

Red Star Line.—Leave every Wednesday for Antwerp; round-trip tickets from $109 to $180, according to size and location of state-room; duration of voyage, about nine days.

Hamburg American Packet Co.—Leave every Thursday for Hamburg via Southampton, England; round trip tickets from $90 to $200, according to size and location of state-room; duration of voyage, about 6½ days.

Norddeutscher Lloyd.—Leave Wednesday and Saturday for Bremen, via Sonthampton, England; single tickets from $100 to 175, according to size and location of state-room; no reduction on round trip tickets; duration of voyage, about seven days.

French Line.—Leave every Saturday for Havre; round-trip tickets from $144 to $216; according to size and location of state-room; duration of voyage, about 7½ days.

You can readily find the office of any of these lines in New York, at any of which every courtesy and information concerning the steamers of the line will be given.

Excursion Tickets.—If you decide to buy an excursion ticket, you cannot do better than to consult with Messrs. Thomas Cook & Son, 261 Broadway, New York, who have supplied us with the following list of "tours" for which they will sell round-trip tickets at the prices affixed.

Tour 1.—New York, by State Line Steamer to Glasgow; rail to Edinburgh, Melrose Abbey (Abbotsford). Carlisle, London, Harwich, Antwerp, Brussels, Cologne. Hanover, Berlin, Rotterdam, Harwich, London, Glasgow; State Line Steamer to New York.

First Class throughout	$143 00
First Class steamers, mixed* R. R.	122 50

Tour 2.—New York, by State Line Steamer to Glasgow; rail to London, Harwich, Rotterdam, Hanover, Berlin, Leipsic, Frankfort, Wiesbaden, Biebrich; steamer down the Rhine to Cologne; Brussels, Antwerp. Harwich, London, Carlisle, Melrose Abbey (Abbotsford). Edinburgh, Glasgow; State Line Steamer to New York.

First Class throughout	$145 00
First Class steamers, mixed* R. R.	124 00

Tour 3.—The same route to Berlin as Tour No. 1; then to Dresden, Carlsbad, Nuremberg, Munich (for Ober Ammergau), Lake Constance, Zurich, Lucerne, Bale, Paris, Rouen, Dieppe, Brighton, London, Glasgow; State Line Steamer to New York.

First Class throughout	$175 50
First Class steamers, mixed* R. R.	145 00

Tour 4.—New York, by Red Star Line Steamer to Antwerp; rail to Brussels, Cologne, Hanover, Berlin. and return to New York by the same route.

First Class throughout	$158 00
First Class steamers, mixed* R. R.	148 00

Tour 5.—The same route to Berlin as Tour 4; then to Leipsic, Frankfort, Wiesbaden, Biebrich; steamer down the Rhine to Cologne; Paris, Rouen, Dieppe, Brighton, London, Rowsley (for Haddon Hall and Chatsworth House). Liverpool, and Inman Line Steamer to New York.

First Class throughout.....$182 50
First Class steamers, mixed* R. R..... 167 50

Tour 6.—The same route up to Frankfort as Tour No. 5; then to Heidelberg, Baden Baden, Strasburg, Paris, Rouen, Dieppe, Brighton, London, Rowsley (for Haddon Hall and Chatsworth House), Liverpool; Inman Line Steamer to New York.

First Class throughout.....$185 00
First Class steamers, mixed* R. R..... 168 50

Tour 7.—The same route up to Berlin as Tour 4; then to Dresden, Munich (for Ober Ammergau), Lake Constance, Zurich, Lucerne, Bale, Paris, Rouen, Dieppe, London, Liverpool, and Inman Steamer to New York.

First Class throughout.....$196 00
First Class steamers, mixed* R. R..... 175 50

Tour 8.—New York, by Anchor Line Steamer to Glasgow; rail to Edinburgh, Melrose (Abbotsford), Carlisle, London, Harwich, Antwerp, Brussels, Cologne, Hanover, Berlin, Dresden, Munich, Innsbruck, Bolzen, Brenner Pass, Verona, Venice, Florence, Rome, Naples; Italian Line Steamer to New York.

First Class throughout.....$229 00
First Class steamers, mixed* R. R..... 201 00

Tour 9.—New York, by Guion Line Steamer to Liverpool; rail to Rowsley (for Haddon Hall and Chatsworth House), London, Harwich, Rotterdam, Berlin, Hanover, Cologne, Brussels, Antwerp, Harwich, London, Leamington (for Kenilworth Castle and Stratford-on-Avon), Liverpool, and Guion Line Steamer to New York.

First Class throughout.....$164 00
First Class steamers, mixed* R. R..... 146 50

Tour 10.—The same route to Antwerp as Tour 9; then to Paris, Rouen, Dieppe, Brighton, London, Leamington (for Kenilworth Castle and Stratford-on-Avon), Liverpool, and Guion Line Steamer to New York.

First Class throughout.....$174 55
First Class steamers, mixed* R. R..... 155 50

Tour 11.—New York, *via* Cunard, White Star, or Inman Line Steamer to Liverpool; rail to London; thence *via* Queensboro and Flushing to Berlin (Royal Mail Route, journey London and Berlin, 26 hours). Returning *via* Dresden, Carlsbad, Nuremberg, Munich (for Ober Ammergau), Lake Constance, Zurich, Lucerne, Brunig Pass, Interlacken, Berne, Lausanne, steamer on Lake to Geneva, rail to Paris, Rouen, Dieppe, London, Liverpool, New York.

First Class throughout.....$242 00
First Class on Atlantic Steamers, second beyond. 215 50

Tour 12.—New York, by Hamburg-American Express Steamer to Hamburg, thence by rail to Berlin, and return to New York the same way.

First Class throughout.....$194 50
First Class steamer, second class R. R..... 190 80

Tour 13.—As tour 11, *via* Hamburg-American ordinary steamer, and return.

First Class throughout. $129 50
First Class steamers, second class R. R..... 125 80

Tour 14.—New York, by North German Lloyd Steamer to Bremen, thence rail to Berlin, return same way.

First Class throughout.....$215 60
First Class steamers, second class R. R..... 211 60

Tour 15.—New York, by Netherlands Steamer to Amsterdam, thence rail to Hanover, Berlin, and return *via* same route.

First Class throughout.....$126 50
First Class steamers, second class R. R..... 120 00

* Mixed class is third class in Great Britain and second class on the Continent.

Note.—The prices shown above are at the ordinary rates. *Reductions* in many cases are made to bona-fide medical men, and in some instances to their wives and families.

All the foregoing tours can be used in either direction, and those reading via Liverpool can be routed by way of Birmingham, with stop-over privileges.

Preparations for the Voyage.—A heavy overcoat, and thick woollen underclothing should be taken to wear upon the steamer, as it is always cool upon the Atlantic; and the comfort of the voyage will usually be much increased by taking a "steamer chair" as it is called, and a rug. The former can be purchased in New York for from $2 to $5, and the latter at from $2 or $3 up.

Information as to your baggage will be given you at the office of the steamer.

As soon as possible after the steamer leaves its wharf, it is well to see the steward and arrange for your place at table during meals. If you think you are likely to be ill during the voyage, a seat on the outside of the table, and as near the door as can be had, is desirable.

No fees are necessary on the steamer until just before going ashore on the other side, when the steward who looks after your state-room will expect a fee of ten shillings sterling (about $2.50), and the one who waits on you at table, a like sum.

Should you have any meals served on deck, the steward who does duty there will expect say four shillings sterling ($1). If you frequent the smoking-room, the attendant will also be on the lookout for a fee. The proper amount for this individual being 2s. 6d., or 60 cents. Last you will find the "boots" who has cleaned your shoes each morning, on the lookout for his "tip" of say 2s. or 2s. 6d. when you are about to go ashore. This, you say, is un-American. We do not believe in fees: but remember you will not then be in America, and for your own comfort follow the custom in this matter, and you will find the result most satisfactory. You may escape the "boots" by wearing a pair of brown leather or steamer shoes, a course followed by many travellers.

Landing in Europe.—Before going ashore you will be provided by the steward with the initial letter of your last name, perhaps four to six inches large, printed on paper already gummed, in sufficient number to paste one upon each article of your state-room baggage, all of which will be taken ashore by the stewards and assorted on the landing pier, together with the baggage of all the other passengers, in groups represented by the same letters. Whatever baggage you may have in the hold of the ship will also be assorted in this way, so that you will have no difficulty in getting together everything that belongs to you.

On landing you will be met by a Custom House official, who will want to know if you have anything dutiable (the only things subject to duty being perfumery, wines, spirits, and tobacco) or any fire-arms, or reprints of copyrighted English works. He will probably make a cursory examination of your baggage. Say nothing, be pleasant, and you will find him the same. If you land at a port where the language spoken is not English, and you are not able to speak it, it will save trouble to look out for "Cook's" agent. He will give you all the information you may need, and will act as interpreter if necessary.

In England.—Should you go via Liverpool, you will find a special train on the Midland R. R., waiting to take you to London, which will be reached in five hours.

In England, most of the railroad trains have first, second, and third class carriages. It is the general custom in England to consider the cost of railway travelling more than is done in America, and, while first class railway fares do not vary much from the cost of travelling in parlor-cars in America, most avail themselves of the lesser cost of travel in the second and third class carriages.

In England, we think you will find it to your advantage to purchase your railroad tickets from place to place only, unless you are quite sure you know exactly where

you wish to go en route from your place of landing to the point of departure for the Continent. In the latter case we would advise you to purchase through tickets from Messrs. Cook & Son.

Travel on the Continent.—When you are ready to leave London for the Continent, if you have not previously bought your ticket direct to Berlin, we would again advise you to mark out your route and get a through ticket to Berlin from any of Messrs. Cook's offices in London.

If you cross the ocean by the French line you will land at Havre, whence a special train will take you to Paris. The North German Lloyd lands you either at Southampton or Bremen, as you may decide before leaving New York. The Hamburg American Co. will take you to Plymouth (Eng.) or Hamburg, and the Netherlands America Co. to Rotterdam, while the State Line will land you at Glasgow. From any of these points you will find your own way to Berlin.

Do not carry too much clothing. Gentlemen will find a couple of suits ample for a two months' trip. Ladies should only take a small trunk, as they will find it very much easier to get along with a small rather than a large amount of baggage. This will apply also to the Customs examinations. It must also be remembered that the railways on the Continent of Europe do not allow as much baggage as the companies do in America. All over the Continent of Europe the railways only allow sixty pounds per passenger, with the exception of Switzerland and Italy, where *all baggage* has to be paid for. In England, first class passengers are allowed one hundred pounds each.

Second class railway travelling is very comfortable throughout Germany and France, and gentlemen travelling alone (without ladies) need never go to the expense of first class fares. In Switzerland it is not at all uncommon to travel third class.

On arriving at the railway station, a porter will come to your carriage and take your trunk to the baggage-room. If you are using Cook's Circular Tickets, you go at once with him; otherwise, you must go to the ticket-office, and be sure you obtain tickets for the place you wish to go to, and the proper class. Then follow the porter to the baggage-room, point out your trunk, and give your ticket to the baggage-man. Your baggage will then be weighed, and after you have paid and taken a receipt for it, your ticket will be handed back to you, together with a small piece of paper, upon which is printed a number corresponding with a similar slip pasted upon your trunk. This, it will be perceived, corresponds with the check system in vogue in this country. It is quite customary, though not obligatory, to pay the man who weighs your baggage a small fee, the equivalent of about five cents, and the porter who carries it into the baggage-room, the equivalent of ten cents. In England, the porter expects a sixpence. If you wish to leave your trunk at the railroad station until you have secured your rooms, it is only necessary to retain the paper check, which can be presented subsequently, when you have ascertained where you will lodge. The porters who run alongside the trains as they arrive at the stations, to carry your baggage to the carriage, expect a fee of the equivalent of from five to ten cents. Before entering a railroad car it is always safer to mention the name of the place you wish to go to, to the guard, to make sure of entering the right compartment. The classes, first, second and third, are always prominently painted on the sides of the car.

For names of hotels to stop at, in all the different places in Europe, it is perfectly safe to follow the advice given in Baedecker's guide books.

During your travels, especially on the Continent, you will find many things very different from what you are accustomed to at home. You will have to provide your own soap, as none of the hotels furnish it. You will usually also find a charge for candles in your hotel bills, even though you may not have as much as lighted them, though in this case, a statement of the fact is sometimes sufficient to have this charge cancelled. To your every expostulation, you will get the reply, "it is the custom of the country." The "portier," whom you will find resplendent in gold lace and buttons, at most hotels, will give you all the information you want, and expect a fee for doing so. When you leave, give him the equivalent of from twenty-five to fifty cents according to the extent to which you have used his services. This worthy speaks all the European languages, and will always be found very obliging.

Obituary.

THOMAS C. FINNELL, M.D.,

NEW YORK.

Dr. Thomas C. Finnell, who years ago was an active practitioner in this city and was deputy coroner for a long period, died of cerebral meningitis, April 9th. He was born in this city in 1826, and studied medicine with Professor Gunning S. Bedford. He graduated from the medical department of the University of the City of New York, in 1849. Twenty years ago he was the examining physician for the Board of Coroners. About that same time he became the attending surgeon of St. Vincent's Hospital. At the outbreak of the war he answered the Governor's call for volunteer surgeons, and served to the end. He was a member of the Medico-Legal Society, the Society of Medical Jurisprudence, the State Medical Society, the Academy of Medicine, the Pathological Society, the County Medical Society, and the Physicians' Mutual Aid Society. He leaves four sons. Two of them are physicians. One of these, Thomas C. Finnell, jr., succeeded to his father's practice two years ago, and the other, James M. Finnell, is in practice in St. Paul, Minn.

Reviews and Notices of Books.

Introduction to the Treatment of Disease by Galvanism. By Skene Keith, M.B., F.R.C.S.Edin., late Special Assistant Surgeon, Royal Infirmary, Edinburgh. London: Truslove & Shirley.

This little work presents in brief compass most, if not all, that it is necessary for the physician to know about electricity in order to be able to employ the agent intelligently in the treatment of disease. The book could be read through in an hour, and there are not very many who would not learn something by devoting this much time to its perusal.

Clinical Lectures on Some Obscure Diseases of the Abdomen. Delivered at the London Hospital, by Samuel Fenwick, M.D., Fellow of the Royal College of Physicians; Physician to the London Hospital. London: J. & A. Churchill. 1889.

These are nine lectures delivered before the senior students at the London Hospital by Dr. Fenwick. In choosing the subjects of these the author selected the cases which he had himself found most difficult to diagnose or treat, or in the management of which he had made some mistake. The book is of special interest at this time when abdominal surgery is making such advances, and when the chief obstacle in the way of its further and more rapid progress is the difficulty of arriving at a correct and early diagnosis of the condition present within the abdomen, and for which relief is sought at the knife of the surgeon. The lectures treat of perforation of the vermiform appendix, stricture of the ileo-cæcal valve, fecal abscess, perinephritic abscess, gastric and perigastric abscesses, tubercular peritonitis in the adult, and cancer and hydatids of the peritoneum. It is hardly necessary to assure those who have ever read any of Dr. Fenwick's published writings that this new work will well repay careful perusal.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON THEORY AND PRACTICE OF MEDICINE.

Stated Meeting, March 18. 1890.

FRANCIS DELAFIELD, M.D., CHAIRMAN.

DR. STEPHEN SMITH BURT read a paper on "Pulmonary Consumption in the Light of Modern Research" (vide page 397).

Pathological Exhibits of Pulmonary Pneumonia and Tuberculosis.—DR. J. H. LINDSLEY gave a "Lantern Exhibition of Photo-micrographs," which included portions of the normal lungs and of the lungs in pneumonia and in tuberculosis. He also exhibited representations of the tubercle bacilli.

Transmission of Disease by Inheritance.—Dr. A. JACOBI said that he would confine his remarks to the question of the direct transmission of the disease by inheritance. We frequently found children who are puny from birth becoming tuberculous at an early age. In others the heart was very small congenitally, so that the circulation was defective. In others, again, there was a congenital smallness of the pulmonary artery, giving the same result. In still others there was premature ossification of the ribs, resulting in a lack of expansion in the chest-walls which certainly crippled the development of the heart and lungs. The condition of the epithelium of the bronchial tubes, which necessarily resulted from insufficient circulation, also rendered the child peculiarly susceptible to morbific processes, such as tuberculosis; while, as long as the epithelium remained normal injurious matter would not be admitted to the lungs.

There were a number of writers who did not believe in the direct hereditary transmission of tuberculosis, and it was indeed a very difficult matter to prove, as there was a possibility of the bacilli of the disease being introduced into the system at a very early period of life, in the food and by other means. Dr. Jacobi quoted the opinions of Bender, Virchow, Epstein, and others, and said that the latter author had reported that in two hundred tuberculous infants he could not find a single one in which direct hereditary transmission was established by positive evidence.

Sometimes Directly Inherited.—On the other hand, there were some circumstances which afforded ground for the belief that tuberculosis is sometimes directly inherited. This had been the opinion held for thousands of years. Bremer's figures, he thought, ought not to be excluded, and Virchow had shown that various drugs as well as syphilis, and other diseases, could be transmitted to the fœtus in utero through the placental circulation. Jongh had found tubercles in the body of a still-born calf whose mother was tuberculous. Dr. Jacobi went on to say that in Keating's "Cyclopædia of the Diseases of Children" he had recently inserted an account of a case which he had met with thirty years ago, and which, he believed, was thus far unique. A fœtus, still-born at seven months, showed the presence of tubercles in the spleen and other organs. He believed, therefore, that there was a possibility of direct transmission. In tuberculous children, if the source of infection had been taken into the system by inhalation or with the food, we would naturally expect that the disease would develop in the lungs or in the intestines. But this was very rarely the case, the tuberculous process being ordinarily located in the glands and the bones. Many of these cases of tuberculous disease are observed in the first year of life, and were apt to last a very long time; and they seemed to afford some ground for the probability of direct hereditary transmission.

How Little Koch's Discovery has done for Treatment of Phthisis.—DR. WILLIAM H. DRAPER said that he confessed to a feeling, not perhaps of disappointment, but, at all events, of depression, when he reflected how little the discovery of Koch has really done toward mitigating the great evil of tuberculosis. If anything, it seemed only to have complicated matters for us. The rôle which the bacilli played did not appear to have been as yet completely made out. In lupus they were found localized without producing general infection of the system. The same was sometimes true also of bacilli in the glands, and when in the latter case they did give rise to infection, it was often not until after quite a long period of time. When the bacillus had its lodgment in the lungs it appeared to produce its most serious results. Yet even here its effects were sometimes quite circumscribed, and it was well known that certain cases of pulmonary tuberculosis recovered. The action of the microbe was not, then, clearly explained. We were told by some that the bacilli secretes ptomaines which do the sole mischief in tuberculosis. Others told us that, in order to be efficient as a cause of disease, the bacillus must meet with and combine with some other organism, in regard to the nature of which nothing is at present known.

How far had the discovery of Koch affected our treatment? At first we had supposed that it would have some great effect as regards the prevention and treatment of consumption. But, unfortunately, we seemed as helpless as ever to act against such a widely extended agent as the tubercle bacillus. We could not destroy it, and we could not escape it unless we fled from regions where the bacilli were found to be especially prevalent. The cautions against the spread of the infection by means of the sputa of tuberculous patients, etc., were undoubtedly most valuable suggestions; but they had not yet been systematically carried out, even in our best hospitals. He did not believe, for his part, that it would ever be possible to control the American habit of expectoration.

Cases Treated in the Same Old Way.—As regards the treatment of phthisis, we now managed cases of the disease in very much the same way that we did before we knew about the bacillus. We could not destroy this bacillus in the body, any more than we could destroy it outside of it. So far as prevention was concerned, however, he thought that the discovery had enabled us to add more weight to our advice to patients to flee from localities where the bacillus abounds in numbers. There were certain regions where they were comparatively unknown, and a residence in such a climate was of the greatest importance in the early stages of phthisis.

That the discovery of Koch was ever destined to help us much in the treatment of this disease after it was well established in the system seemed to him very unlikely. He confessed that the outlook was discouraging as regards phthisis that was well advanced.

DR. ANDREW H. SMITH said that he shared to a considerable extent the discouragement which Dr. Draper had expressed. He thought that while the search for some germicide to combat the tubercle bacillus should not be altogether given up, this should not be made so prominent a feature of our efforts as to lead us to give up the employment of other methods that might prove useful in dealing with the disease. While this search had been going on it seemed to him that we had lost something in slighting other means of treatment. Still, it did not appear unnatural to hope that the time would come when some means would be discovered which, if it would not destroy the bacilli, would at least limit the facility with which they propagated.

Positive Danger from Contagion.—One great benefit resulting from Koch's discovery was that we were now in a position to say to our patients that there is a positive danger from contagion in this disease. It had been his lot to observe the history of many cases of consumption among the population in rural districts, and he believed that the mortality in such cases was not due so much to heredity as to the environment in which these individuals lived. He had been particularly impressed with the prevalence of the disease in certain families; one mem-

ber after another being successively carried off by it. It might be that some of the older children would marry and move away from the paternal home before the disease had invaded it. Then one of the younger members of the family would contract phthisis at school or elsewhere, and from that time on one child after another would be taken down with the disease as soon as they reached a certain age, until out of a large family only the parents perhaps might be left alive.

Such unhappy results he believed are due largely to the mode of life in the country, notwithstanding the fact that naturally the locality might be perfectly salubrious. Among the rural population the sleeping rooms were commonly very small, and two persons usually slept in each. The admission of air into the house was generally regarded as the greatest element of danger to health, and the entire winter was apt to be passed with scarcely any ventilation. Furthermore, there were but few of the changes in the household which were so frequently made in the city. The furniture and the hangings, etc., which were generally of such a material as not to admit of washing, were left unchanged for several generations, it might be; and the conditions were thus all most favorable for the continued harboring of disease-germs. Now, if we could say to these people that consumption was a distinct entity due to a specific microbe, we would have a very strong argument with which to enforce the observance of suitable precautions about the household.

Low Grade of Tissue-cells most to be Feared.—But aside from this, we come to the point that a low grade of tissue-cells, rather than tuberculous disease itself, was transmitted by tuberculous parents to their offspring. Hence, as Dr. Burt had emphasized in his paper, it was of the utmost importance that we should begin early with the children of such parents in our efforts to improve their nutrition and strengthen their vital powers. Hence it was necessary, from a sanitary as well as a moral point of view, that parents should learn to control their children, and not permit themselves to be overruled, as was so commonly the case among the indulgent.

Nothing had so far been said as to the relation of bronchial catarrh and tuberculosis, as he had hoped. It had seemed to him that bronchial catarrh was often the starting-point for tuberculosis; but whether there was anything more in this apparent relation than the fact that the condition of the mucous membrane in this affection offered a favorable place of lodgment for the tubercle bacilli was a question which as far as he knew had not yet been determined. If the epithelium were in a normal condition, as Dr. Jacobi had stated, noxious material could not well be taken into the lungs; but bronchial catarrh was frequently due to faulty environment, and as the epithelium readily became impaired, it could be seen how important it was that children especially should be kept as free as possible from all influences tending to lower the vitality.

Supplemental Alimentation.—As to the treatment of phthisis, he desired to speak particularly of the importance of supplemental alimentation by means of the rectum. This was a means of increasing the nutrition which ought not to be neglected, and he had personally seen some very remarkable results from this practice.

Necessary to have a Favorable Soil for the Development of the Seed.—Dr. R. C. M. Page said that any condition or combination of circumstances that would produce the requisite degree of lowered vitality in any given case, would furnish a favorable soil for the reproduction of the tuberculous virus. He would not stop to consider the various causes of lowered vitality, but it might be acquired or inherited. This inherited predisposition to a condition of lowered vitality, including narrow chest, imperfect heart and arteries, as alluded to by Dr. Jacobi, would seem, other things equal, to furnish a more favorable soil for the growth and proliferation of bacillary germs of tuberculosis than such a condition acquired in a person previously healthy. But there was no doubt, from daily observation in practice, as well as from experiments, that in either case infection with tuberculous virus may occur in a number of ways—chiefly, he thought, through the inhalation of air containing the germs in dried sputa. But according to the experiments of Chauveau, Villemin, Tappeiner, and others, from 1867 to 1876, this virus may be transmissible not only by the respiratory and digestive tracts through infected air or food, but also by subcutaneous inoculation, the integument stripped of its epidermis, the conjunctiva, and genito-urinary tract; by dermatoses, which destroy the epidermis; through sudoriparous and sebaceous glands; and, finally, through wounded and absorbing surfaces.

Among foods, milk, and especially cow's milk, was undoubtedly a vehicle for infection in this disease, for although practitioners in general had not followed up this source of infection to the particular cow from which it came, the matter had been sufficiently proved by scientific experiment to place it beyond doubt. For this reason in the city of Paris it is now the universal custom to boil all cow's milk before using it.

Ovule may Become Infected.—Not only does inheritance furnish a vulnerable point for vagrant tuberculous germs in the way already referred to, but according to the experiments and observations of Landouzy and Martin, of Paris, the ovule may have tuberculosis communicated to it directly through bacillary germs, or sporules, contained in the spermatozoa. In one such case, observed by them, the father and children died of the disease, the mother escaping.

He thought that the author of the paper was evidently correct in the statement that treatment is futile so far as there is any particular antidote. At most the treatment by medicines was symptomatic, the real cure, when it did occur, being effected more by climate, diet, and hygiene in general.

Regarding prophylaxis, the persistent destruction of infectious material, as indicated by the author, was of the utmost importance. Unfortunately, as Dr. Draper had observed, it was difficult, if not impossible, to regulate expectoration, and for that reason infectious matter, though it may be limited, could not be exterminated except in hospital practice. Marriage between consumptives, on the other hand, could and should be prohibited or restricted. In this way the chief source of a favorable soil for tuberculous germs would be cut off.

Finally, if the means of curing tubercular pulmonary consumption be found, there remains the great importance of early diagnosis and treatment, since after the organs of respiration become involved in pathological changes, with more or less loss of tissue, there are other serious conditions left for consideration even though the virus has been counteracted.

Simply a Step Onward.—Dr. J. West Roosevelt said it seemed to him that the most important thing for us to remember regarding the "light of modern research," as far as it concerned consumption, was, that it is as yet a faint and uncertain light—a dawn, as it were, which, though it promises the sun, gives but a dim, mist-obscured view. The proof of the bacterial origin of phthisis simply led us a step onward. It should not change our practical ideas of the disease save as regards one point, namely, prophylaxis. As Dr. Burt had said, there was danger in living with phthisical patients. The destruction of expectoration was easy, and there was no more reason for not destroying the bacillus than for keeping strong poison on hand within easy reach of every child, and in a place where it was likely to get into the family food. We should instruct our patients to expectorate into the fire, or into receptacles that could be readily emptied into the fire; and this would at all events do something toward preventing the spread of the infection. It was true that tuberculosis was in a measure a self-limited affection; but, unfortunately, this self-limitation was frequently not reached before the unhappy subject of the disease died.

The Absurdity of Antiseptic Treatment.—The absurdity of so-called antiseptic treatment, based upon the usual experiments with germicides, was now fairly well appreciated, as had been clearly stated by Dr. Burt. It seemed that the acme of preposterousness had been attained when it was suggested to try to kill the bacilli by means of gaseous enemata—to "boost" them out, as it were. Some time ago, in a short paper before this Section of the Academy, Dr. Roosevelt said he had ironically suggested that it would, perhaps, be well to heat up a patient, and thus destroy the bacilli in him; and had remarked that there was a small difficulty in the way of carrying out this procedure, namely, the roasting of the patient. He did not then know that the hot-air method of treatment would seriously engage the attention of the profession. It was hardly conceivable that any one should think that the air within the lungs could be heated much above 100°. If it were, the whole body temperature would rise proportionately, since all the blood had to pass through the lungs. Moreover, the actual amount of air inspired and exhaled was very small compared with the quantity of residual air. The amount of heat lost merely in passing through the upper air-passages and large bronchi must be enormous. Moist tubes with a large surface surrounded by a moving fluid at a temperature of about 100° would lower the temperature of an enormous bulk of air.

Inhalation of Dry Hot Air.—If the temperature of the air in the lungs should be raised sufficiently to kill the bacilli, the fluid in which they lay, whether they were in the tissues or the expectoration, must be raised to a corresponding extent; and this means coagulation of many albumins. Dry hot air was very different in its effect from moist hot air. While the latter would scald the upper air-passages, dry hot air could be inhaled without injurious effects at a considerably higher temperature than that at which the moist air would produce scalding. It seemed, then, that after making our search after antiseptic agents to destroy the bacilli we are left in the same position as before.

In organic chemical compounds, however, we might hope, perhaps, that something could be found which would increase the power of blood-serum to kill microbes, since there was already some reason to believe that the blood-serum possesses a certain quality which for a short time renders it capable of destroying the bacilli.

Mode of Infection.—As to the mode of infection in pulmonary tuberculosis, nothing was as yet satisfactorily established. At present we could not understand why the upper lobes of the lungs should be primarily attacked. While it was true that these parts did not get as much air as other portions of the lungs, it was also true that on this account they must necessarily take in fewer bacilli. On the other hand, bronchial catarrh not infrequently seemed to precede general disseminated miliary tuberculosis of the lungs; and this would seem to offer a good example of infection.

What, after all, was the use of this discovery? Its use was already much more apparent than was for a time that of many other things which at first seemed to be of little or no importance, but which had afterward proved of the highest service to mankind. Thus, the Alexandrian philosophers worked for years and years over abstruse problems in their geometrical studies, which seemed to have no practical value whatever. Yet upon the results of these same mathematical studies the whole modern system of navigation was founded. If by our knowledge of the more or less contagiousness of phthisis we are able to save a few lives, this knowledge was worth having; and the discovery of its bacterial origin had already given us a basis upon which there might perhaps in the future be built up a successful treatment, curative as well as prophylactic.

Koch's Discovery not much of a Help in Treatment.—Dr. Charles E. Quimby said it seemed to him that the discovery of Koch had given us a light which was something far more than the faint dawn which Dr. Roosevelt had spoken of. It was true that it had not as yet helped us in the treatment of phthisis; but it had taught us what we cannot do. It had brought us back to the point that it is the patient himself that must work out his cure and that the physician can stand by his side and help him do it. He had seen enough in his experience to convince him that there are many other kinds of treatment which are better than mere change of climate. Pure air was certainly good of itself, but it was not the only thing to be taken into consideration. In every case of threatened phthisis it was important to begin by laying down an outline of dietetics and of the entire mode of life to be followed. This was to be done the moment that the patient exhibited, not signs of tuberculosis, but a tendency to the disease. In the search for some method of antiseptic treatment, it was natural that various expedients, such as the inhalation of hot air, should be suggested; but all such inadequate measures had now been happily relegated to their true position.

The Mortality of Phthisis in Rural Districts.—Dr. Edward F. Brush said that the statistics of tuberculosis in agricultural districts did not give us any idea of the real mortality from the disease there. We often heard of the comparative immunity of rural populations from it; but this was an entire mistake, and was due simply to the fact that the records of vital statistics were not kept with the same accuracy as in cities, so that many individuals were buried without any death certificate whatever. Personally, he knew of many agricultural districts where the death-rate from phthisis was as large as in the city.

Tuberculosis not Communicated to Living Offspring.—As to the matter of heredity, he had devoted special study to the question for a long time, and he believed that the fact remained uncontroverted that no authenticated instance had yet been recorded in which tuberculosis had been conveyed from a parent to a living offspring. In the case related by Dr. Jacobi, as in that of the calf reported by Dr. Jongh, the offspring was born dead. Some time since he had shut up six hens and a cock, and fed them exclusively on tuberculous lung from a cow. One of the hens was afterward found to be tuberculous; the tubercle bacillus being demonstrated in her body. The eggs laid by these hens, twenty-six in number, were taken to another part of the farm and set under two hens. Twenty-five of these eggs developed chickens, but not one of the twenty-five chicks came out of the shell alive. Of course, that experiment should be repeated, and he intended to try it again. Although all the chicks were dead, none of them presented any gross evidences of tuberculosis. No microscopic examination had been made.

A Plea for Ovarectomy.—Among cows there was a class known as "bullers," because they were in heat all the time, and this class never became pregnant. From three such cows he had removed the ovaries, and a tubercular condition was found in each of them. He had seen a great many calves from tuberculous cows, but he had never yet found the gross evidences of tuberculosis in one of them.

In closing the discussion Dr. Burt said that his hopes for the future as regards phthisis were based on what had taken place in the past, and that he did not expect as much from any specific kind of treatment as from the prevention of the disease.

Balsam of Peru and the Kidneys.—Nothnagel and Rossbach have asserted that the administration of balsam of Peru internally, excites an inflammation of the stomach, intestines, and all mucous membranes, and acts injuriously upon the kidneys. In order to determine the correctness of this assertion, Drs. Bräutigam and Nowak made a number of experiments, with absolutely negative results. They gave as much as three drachms a day for three weeks without being able to observe any trouble whatever of the stomach or kidneys. The urine was not discolored nor was its quantity changed at all.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, February 26, 1890.

H. P. Loomis, M.D., Vice-president, in the chair.

Generalized Tuberculosis, Having its Origin in the Intestine.—Dr. William P. Northrup presented some specimens illustrating this condition, which were removed from the body of an infant which had died in the Foundling Asylum at the age of fifteen months. The child had been healthly up to the age of nine months, at which time it began to droop. Before death it had a cough, moderately high temperature, and diarrhœa. Upon autopsy the liver, spleen, and kidneys were seen to be tuberculous to a moderate degree, the lungs but little affected, and the brain and meninges not at all. Opposite the middle of the ileum, within the mesentery, were eight to ten large lymph-nodes, closely grouped together; these were cheesy and had diffluent centres. The mesentery was somewhat shortened and thickened at this point, and the intestine was sharply doubled on itself, forming a knuckle, its contiguous walls being adherent. Two sinuses, having their openings in the legs of the knuckle, passed down into the thickened and contracted mesentery in a V-shape and terminated together in a cul-de-sac. A bent probe could be easily passed into one sinus, dipping down into the mesentery, and made to emerge at the other sinus. In this knuckle of ileum was a single ulcerated Peyer's plaque, the ulcers having characteristic edges. Here, then, in immediate juxtaposition were ulcerated plaque, old sinuses, thick and contracted cicatrix, cheesy and diffluent lymph nodes. No ulcer was observed in any other part of the ileum, and the enlargement of the mesenteric lymph-nodes, apart from the group just described, was but moderate, and none were cheesy or tuberculous. The colon was the seat of extensive chronic catarrhal inflammation. Examination under the microscope showed thickening of the mucosa and superficial necrosis of the epithelium. The large mesentery lymph-nodes near the sinuses were found to be tuberculous. The only cheesy lymph-nodes in the body were in the mesentery immediately about the cicatrix and old sinuses. The tubercles in the other organs were small and presumably recent.

Dr. Ely asked whether anything was known about the nurse to whose care this child had been confided, and whether any examination had been made of her breasts; he also asked what was supposed to be the cause of death, whether it was not from exhaustion in consequence of the abscess, and finally he enquired if Dr. Northrup considered the abscess to have been primary.

Dr. Northrup said that every effort had been made to ascertain something concerning the health of the nurse, but without success. The cause of death was thought at the time to be dysentery. In reply to the third question, the speaker thought that the abscess was primary.

Dr. Ely said he thought that this case was of exceeding interest in the bearing that it had upon the etiology of tuberculosis. It was to be presumed that this child had never had anything in the way of nourishment except breast-milk. Many investigations had been made both in this country and in Germany to determine the conditions of the transmission of tuberculosis by means of milk, and some had maintained that the milk might contain tubercle bacilli even when there was no disease of the udder. Dr. Ernst claims to have found cases in which there were no lesions discoverable in the udder, and yet there were tubercle bacilli in the milk. It would therefore be exceedingly interesting to have accurate information concerning the health, and especially the condition of the breasts, of the nurse who had the care of this infant.

Caries Necrotica of the Astragalus.—Dr. T. H. Myers presented a specimen removed by operation from a child, three years old, eight months after a diagnosis of tuberculous synovitis of the ankle-joint had been made from the symptoms present. The joint was not properly treated, owing to family reasons, and two months ago two sinuses opened on its inner aspect, through which carious bone was detected. The parents being unable and unwilling to carry out conservative treatment, operation was decided upon. Through lateral incisions the astragalus was shelled out of its cartilages and periosteum without the exercise of any force whatever. The cartilaginous surfaces appeared smooth, but the synovial membranes were pulpy. There were also extensive deposits of tubercular granulations beneath the anterior tendons, and on both lateral aspects of the joint. From the specimen it would seem that the disease was originally peripheral. The specimen also showed the necessity of a radical operation if any were attempted.

Sub-dural Hemorrhage.—Dr. E. D. Fisher presented a specimen of extensive sub-dural hemorrhage which had given rise to few or no symptoms. The specimen was removed from the body of a man who had died of general tuberculosis. Twenty years before his death he had received a blow fracturing the frontal bone, but recovered perfectly, and was able to return to his work in eight weeks. Upon removing the skull a mass was seen beneath the dura mater, covering and pressing upon the greater part of one side of the cerebrum, involving the face and mouth centres. It was interesting that such an extensive meningeal hemorrhage could have occurred, becoming encysted and organized without exciting any symptoms of a permanent nature.

Thrombosis of the Cerebral Sinuses.—A second specimen was one removed from the body of a woman who had been under treatment for what was supposed to be acute mania. But little was known of the woman's previous history, further than that she had been addicted to the immoderate use of alcohol. The symptoms were the ordinary ones of acute mania, except that there had been no rise of temperature before death, as is so common in these cases. Upon autopsy all the organs were found to be normal, with the exception of the heart. The walls of the right ventricle were rather thin, though the speaker was not certain that this was a pathological condition. The pulse had been found to be somewhat intermittent and feeble toward the end of the patient's life. In the brain a thrombosis was found, involving almost all the sinuses and also of the veins entering into the brain. This thrombosis was undoubtedly of ante-mortem formation. The finding of this very extensive thrombosis in connection with symptoms of acute mania was interesting, as Dr. Fisher did not know of any signs by which the presence of this intra-cranial condition could be diagnosed. The speaker doubted whether the woman had acute mania, but believed that the symptoms were caused by an interference with the return circulation from the brain.

Dr. Northrup has seen two cases of thrombosis of the longitudinal sinus occurring in children. In one of the cases the mother of the infant was suffering from puerperal fever. In both cases the circulation was very weak.

Dr. Loomis said that it was not uncommon to find thrombosis of the longitudinal sinus, and he had never attached any special significance to the condition. They are usually considered to be ante-mortem in their occurrence, being formed just before death.

Dr. Fisher said that the autopsy in this case was witnessed by several persons, and all regarded the thrombosis as having occurred some time previous to death. In this instance the mania would be accounted for by the lesions found post mortem, but he did not believe that it would have been possible to diagnose the condition before death. The post-mortem findings in acute mania were not usually satisfactory, and there was nothing which could be called characteristic of the disease.

Dr. Loomis said that he had been called upon some time ago to make a very careful examination in a case of acute mania, and he had found absolutely nothing except capillary congestion.

Perforating Typhoid Ulcer.—Dr. John S. Ely presented a specimen, for which he was indebted to Dr. J.

S. Thacher, removed from the body of a boy nineteen years of age. He was admitted to St. Luke's Hospital on December 28, 1889, complaining of symptoms pointing to typhoid fever. From that time his disease ran the regular course of a mild case of typhoid fever, the temperature reaching a maximum on the sixteenth day, and coming down to normal on the twenty-fifth. The next day it began again to rise regularly, and in four days reached 105° F., when it became evident that he had a relapse. Ten days the temperature rose with a chill to 105° F. in the morning, and then rapidly fell to 102° F., the patient evincing much shock. Tympanites, and tenderness, pain in the abdomen, repeated vomiting, thoracic respiration, and disappearance of dulness over the liver, all rapidly developed. These symptoms continued for two days, when the temperature rose to 107° F., and the patient died of exhaustion.

At the autopsy typhoid ulcers were found in the ileum, one of which, situated about a foot above the ileo-cæcal valve, was found to have perforated and given rise to a general peritonitis.

Peritonitis, occurring as a complication of typhoid fever, Dr. Ely said, is of one of two varieties : it may occur as a result of perforation of the gut, as in the present instance, or independently of any such perforation. The source of the latter, the so-called idiopathic complicating peritonitis, has given rise to much speculation. A study of the complications of typhoid fever has shown that many of them are caused by the typhoid bacillus. Thus the bacillus has been found by various observers in the following diseases, complicating this affection : lobar pneumonia, orchitis, abscess of the leg, periostitis, nephritis, empyema. Finally A. Fränkel reported a case of typhoid fever in which two attacks of localized peritonitis occurred as complication and sequela, with the subsequent formation of an abscess in the pus, from which no other microorganism than the typhoid bacillus could be found either morphologically or by cultivation. All this suggests strongly the possibility that in certain cases the peritonitis complicating typhoid fever may be caused by the typhoid bacillus. We should naturally expect this to occur in a much larger proportion of cases of peritonitis without perforation than of cases with perforation, since the latter condition permits of the escape into the peritoneal cavity of so many other inflammation-producing agents (most of them more rapidly acting) from the interior of the gut. In view of the possibility of the typhoid bacillus setting up purulent inflammation, search was made for it in the present case both in the ulcerated Peyer's patches and in the peritoneal exudate, but, unfortunately, sufficient time had elapsed after death for putrefaction bacteria to invade the tissues in large numbers, and the question as to the etiology of the peritonitis must therefore be left uncertain. The late occurrence of the perforation, on the thirty-ninth day, and its happening in the course of a relapse, are interesting features of the present case.

Intussusception of the Ileum in an Adult.—Dr. H. S. Stearns presented a specimen removed from the body of a woman, twenty-seven years of age. She was pregnant, and entered hospital January 29th, complaining of pains in the abdomen, but these ceased later in the day. She had a persistent cough, and two days after admission a profuse diarrhœa set in. About three o'clock on the morning of February 3d she was delivered of a dead fœtus six or seven months old. Everything progressed favorably until ten o'clock that morning when the woman began to show signs of shock and failed rapidly in spite of active treatment, and died the same afternoon. During the entire time that the patient was in the hospital she had a weak and rapid pulse and a temperature of 101° F. At the autopsy there was found to be consolidation of the upper half of both lungs, due to miliary tuberculosis, and there were several tuberculous ulcers in the ileum and jejunum. An intussusception was found in the ileum about eight inches above the ileo-cæcal valve. The invagination proceeded from below upward, about four inches of the gut being involved. There was complete occlusion.

A New Bacillus Found in the Air.—Dr. J. M. Byron presented some cultures of a new bacillus which he had discovered. The bacillus gave a red culture in all media. Spectroscopic examination gave one broad line between E and D, and another very far over toward the violet.

Dr. Charles N. Dowd reported the results of a number of examinations of the blood in influenza. Klebs found a number of mobile bodies in the blood of influenza patients, but the speaker had examined several cases very carefully and had not been able to detect the presence of these monads. The cases were mild ones, and the blood was dried before it could be examined. In Klebs' cases the blood was still fluid.

The Society then went into executive session.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 30 to April 5, 1890.

By direction of the Secretary of War, a board of medical officers, to consist of Colonel Edward P. Vollum, Surgeon ; Major George M. Sternberg, Surgeon ; Major Henry McElderry, Surgeon; Captain John J. Cochran, Assistant Surgeon, is constituted to meet in New York City, on April 28, 1890, or as soon thereafter as practicable, for the examination of Assistant Surgeons for promotion, and of candidates for admission into the Medical Corps of the Army. The Board will be governed in its proceedings by such instructions as it may receive from the Surgeon-General. S. O. 78, Par. 6, A. G. O., April 3, 1890.

Mason, Charles F., First Lieutenant and Assistant Surgeon. By direction of the Secretary of War, he is granted leave of absence for two months, to take effect on or about April 15, 1890. Par. 3, S. O. 76, A. G. O., Washington, D. C., April 1, 1890.

Taylor, Marcus E., Captain and Assistant Surgeon. The leave of absence for one month granted him by Par. 3, S. O. 26 c. s., Headquarters Department of the Columbia, is hereby extended one month, on surgeon's certificate of disability. Par. 1, S. O. 19, Division of the Pacific, March 27, 1890.

Skinner, J. O., Captain and Assistant Surgeon, Fort Ontario, N. Y. Leave of absence for one month is hereby granted him, the leave to commence forthwith as his services may be required with troops to change station early in May. Par. 5, S. O. 75, Division of the Atlantic, April 2, 1890.

Official List of Changes in the Medical Corps of the United States Navy for the week ending April 4, 1890.

Ferebee, N. McP., Surgeon. Ordered to the Essex.

Anderson, Frank, Passed Assistant Surgeon. Detached from the Dolphin and ordered home.

Griffith, S. H., Passed Assistant Surgeon. Detached from Museum of Hygiene and ordered to the Dolphin.

Heffenger, A. C., Passed Assistant Surgeon. Ordered to temporary duty at Navy Yard, Portsmouth, N. H.

Simons, Manly H., Surgeon. Ordered to superintend repairs at Widow's Island Hospital, in addition to present duties.

Sulphonal is recommended for chorea by Dr. A. John Jeffreis, of Boston (*Medical News*). He gives it in about five-grain doses.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 5, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	8	3
Scarlet fever	73	14
Cerebro-spinal meningitis	1	4
Measles	249	13
Diphtheria	94	28
Small-pox	0	0
Varicella	9	0
Cholera	0	0

A New Form of Surgical Dressing.—M. Roux, of Paris, proposes to abolish the ordinary method of dressings, which he regards as useless and troublesome, and to substitute a modified form of dressings. He has employed two methods with very good results, the *pansement suturé* and the *suture pansement*, both dressings being made with gauze saturated with sublimate, and again steeped in sublimate at 1 per 1,000. The *pansement suturé*, which is applied exclusively to wounds which are not drained, consists of a band of iodoform gauze covering the suture line, and one or more bands saturated with corrosive sublimate or compresses. The last of these is fixed to the skin by a stitch at each corner. These dressings, which are easily applied, allow the regions surrounding the wound to be watched. If necessary, they are wetted again with the solution at 1 per 1,000 after a day or two. The *suture pansement*, employed for wounds which close by the first intention only, consists of a double band of iodoform gauze, from two to two and one-half centimetres wide, which is placed on the exterior edge of each lip of the wound, and enclosed in the cutaneous suture. The operator begins with a knotted stitch, and unites the basis of the adjusted fragments by passing the needle through a small india-rubber tube between each stitch. When he has reached the end of the wound he returns backward, adjusting the edges of skin in making them overlap. The thread is tied with the tail which remained free at the starting-point. In order to remove this dressing the band is raised by one of the corners, and all the threads which are discovered on one side of the cicatrix are easily cut. In removing the other half the portions of threads which are inserted in the flesh are carried away. M. Roux considers that these dressings may be substituted with advantage for the ordinary method employed. But, as he allows that they can only be efficient when applied in localities and by persons absolutely free from microbes, it cannot be expected that they will entirely replace Lister's dressings in the present day.—*The British Medical Journal.*

A Legal Definition of Total Helplessness.—A bill has been introduced into the United States Senate defining "total helplessness" as applying to all persons who lost a leg or an arm at or so near the joint that an artificial limb cannot be used, and granting all such persons a pension of $72 per month.

A Curious Story is reported from Paris (*Medical Press*), showing the difficulties and ambitions of a medical man: A young man of very humble origin worked his way up by perseverance to a certain education, and finally was able to take out the diploma of *officier de santé*. After two or three years' practice his ambition led him to desire the *doctorat*, but to obtain the higher degree he would be obliged to pass the preliminary examination equivalent to our B.A. He had a bosom friend who was a "grinder" for this examination and who had enabled many others to pass. This friend offered to represent the *officier de santé* out of pure friendship and with otherwise the most disinterested motives. Accordingly he left Paris and presented himself at Lyons, where he thought detection would be impossible. However, not only was his answering extraordinarily good, so as to arouse suspicion, but ill luck would have it that two of the examiners were formerly his own pupils! The trial took place, as already said, last week, and although the prosecution demanded two years of prison, the jury took a very lenient aspect of the case and acquitted them both.

The Itch in Paris.—The French metropolis is great in many things, and it leads the world in the matter of *acari*. The number of cases of itch at one hospital, the St. Louis, in 1878, was 3,809; in 1886 it was 5,987. "These figures," says M. Fournier, "are eloquent," in which we agree with him; but he adds, "they need no comment;" and here we must differ with him, for it seems to inhabitants of this modest and provincial metropolis, where habits of cleanliness are still held in high esteem, that a great deal of comment is needed.

Virchow has made an attack upon the word "luetic." It was, he says, "originally a Leipzig discovery, but it has developed to the rank of a Germanism. It is etymologically incorrect. Lues is a Latin word through the Greek, and means pestilence, not syphilis, and "luetic" cannot by any possible twisting be properly derived from it. Still it is convenient and euphemistic, and enables the physician to refer to syphilis without alarming the patient.

The Doctor was in Luck.—A patient in Warsaw, not long ago found himself unable to pay his doctor's bill, and offered a lottery ticket in exchange in full. The doctor made the best of a bad bargain and accepted the ticket, and has now received his reward in the shape of a prize of $40,000 which the ticket has just drawn. There is no special moral to this story that we have been able to discover.

Cheap Practice in Russia.—A medical club has recently been organized in Tiflis, Russia. It consists of 125 families, 25 of whom are treated gratuitously. The remaining 100 pay each one rouble (fifty cents) a month to the physician of the club, who thus receives about $600 per annum for his services. In addition to caring for the members when sick this obliging, or needy, doctor has agreed to visit each of the families regularly, to inspect their dwellings, and to advise them from time to time in regard to their mode of living. He is also to deliver a certain number of lectures to the members of the club on matters relating to physiology and hygiene. Competition in Tiflis must be active, or else living must be very cheap.

They Starved the Visitors.—Not long since a committee of the Washington legislature made a trip to an asylum in the State. They were received very politely and treated with much courtesy, but the food that was served out to them during their stay was of the poorest quality and very meagre in quantity. It was made to appear that the appropriation for the support of the asylum was insufficient, and that consequently there was no means of getting anything good for the entertainment of the visitors, and it was hoped that the prayer for greater liberality would meet with a gracious approval from the men who had suffered so much from the poverty of the institution. Unfortunately, however, some of the committee were of an inquiring mind, and went quietly by themselves to inspect the condition of the larder and found it well filled with good things to eat. In the asylum bill which the legislature passed at the suggestion of the committee, the salary of the superintendent was cut down $250. This is the sad tale as related by the *Post-Intelligencer*, of Seattle, and if it is true the superintendent has our deepest sympathy.

Medical Politicians.—The French Chamber of Deputies contains forty-eight physicians, one veterinary surgeon, and one dentist.

A New Way to Collect Bills.—A Kentucky doctor is suing a man for medical attendance on his wife during her final illness. There is nothing very unusual in this, but some of the evidence offered is peculiar. It consists of a bundle of letters which the doctor alleges the deceased woman wrote to her husband from the other world, acknowledging the obligation and urging her husband to overcome his meanness and dishonesty for once and pay the just debt.

Paradoxical Pupil-Reaction.—At a recent meeting of the Gesellschaft der Charité-Aerzte, Herr Henoch brought forward a patient with a peculiar anomaly of the left eye, which had previously been operated upon; namely, dilatation of the pupil on exposure to light, and contraction in the dark. The same dilatation of the left eye occurred when the right eye was illuminated, and the same contraction when the right eye was then darkened. The patient was a man who was admitted in 1888 into the new Charité Hospital on account of some syphilitic plastic iritis. There was much exudation into the anterior chamber, the tension of the eye reached a high degree, the pupil being quite closed, so that permanent blindness from secondary glaucoma was feared, and iridectomy was necessitated. Severe hemorrhage resulted on incision, and the operator introduced the iris forceps but could not be certain about what was exactly done, the parts being hid from view. By next morning absorption was rapidly proceeding and a very satisfactory coloboma had arisen. The case went on very favorably, and the patient was dismissed with a visual acuity of one-eighth. Next year he attended again with tertiary symptoms, when the above phenomenon was observed. The simple explanation is that by the operation the sphincter iridis was completely cut through inferiorly. The sphincter contracts together as usual when illuminated, but this now causes a wide gap inferiorly, having the appearance of pupillary dilatation. —*British Medical Journal.*

Widening the Field of Woman's Usefulness.—Quite recently, the *Hospital Gazette* states, a man applied to the house surgeon of a London hospital to have a large hydrocele tapped. He stated that he had had the operation performed at another hospital, but the last time he applied there a young woman operated on him. He had no fault to find as to the way it was done, but he objected to exposing his infirmities to a class of ladies.

A Welsh Medical School.—An effort is being made to establish a medical school at Cardiff in connection with the University of South Wales and Monmouthshire.

Death following a Urethral Injection of Cocaine.—Simes, in a recent number of the *Gaz. degli Ospitali*, records a somewhat remarkable case of death occurring after an injection of cocaine into the urethra. The patient was a man of twenty-eight years of age, and preparatory to undergoing the operation of internal urethrotomy, had a grainme of a twenty per cent. solution of cocaine injected into his urethra. Saving his urethral stricture, the patient was in excellent health. Immediately after the injection the following phenomena supervened, namely, contraction of the muscles of the face, dilatation of the pupils, stoppage of the breathing, and violent epileptiform convulsions. The convulsive signs continued to increase in severity, the respiration became more and more feeble, cyanosis became intense, and at the end of about twenty minutes, despite every care, the patient died. At the autopsy the lungs were normal, but extremely congested; the left ventricle contained no blood.—*The Medical Press.*

No Irish Need Apply.—The London hospitals, in their recent advertisements for internes, have in many instances added the condition that the applicant must be a fellow or member of the Royal College of Physicians or of Surgeons, thus barring out the Irish and Scotch graduates. The latter are, as may be imagined, somewhat indignant.

The Utility of Vaccination.—The deaths from smallpox in Germany during the years 1887–88, were 1.8 and 0.8 per million respectively; in Austria, for the same years the deaths were 583.7 and 540.4. In Germany, vaccination is compulsory, in Austria it is not.

Suspension in the Treatment of Diseases of the Spinal Cord was first employed by Mochutkovski, of Odessa, in 1883.

Prevention of Nicotine Intoxication.—M. Gautrelet has contrived an arrangement of the tobacco-pipe by which the smoke is filtered through cotton-wool charged with pyrogallic acid, which does not affect the flavor of the tobacco, but neutralizes the usual unpleasant effects. —*Provincial Medical Journal.*

Wood as a Source of Human Food.—In an address at Heidelberg by Victor Meyer, it is announced "that we may reasonably hope that chemistry will teach us to make the fibre of wood a source of human food." What an enormous stock of food, then, will be found, if this becomes possible, in the wood of our forests or even in grass and straw! The fibre of wood consists essentially of cellulin, $C_6H_{10}O_5$. Can this be made to change into starch? Starch has exactly the same percentage composition, but, as everyone knows, it differs very much in its properties, and the nature of its molecule is probably much more complex. Cellulin is of little or no dietetic value, and it is not altered, like starch, in boiling water. It readily gives glucose when treated with strong sulphuric acid, as is easily shown when cotton-wool, which is practically pure cellulin, is merely immersed in it Starch gives the same product when boiled with weak acid. The author further quotes the researches of Hellreigel, which go to show beyond dispute that certain plants transform atmospheric nitrogen into albumin, and that this process can be improved by suitable treatment. The production, therefore, of starch from cellulin, together with the enforced increase of albumin in plants, would, he adds, in reality signify the abolition of the bread question. It must be borne in mind, however, that theory, fascinating and promising though it may be, is not always capable of being followed up by a practical result.—*The Lancet.*

Suicides in Berlin.—During the month of January there were seventy-five suicides (fifty-three men, twelve women, and ten children) in Berlin. This is said to be the largest number ever reported there during a single month.

Physicians in Japan.—It is stated, on what authority we do not know, that there are 40,321 physicians in the Empire of Japan. The population of the country is put down at about 40,000,000.

Ringing to Grog.—In olden time in Portland, Me., everybody took a drink about eleven o'clock, and that none might forget to do so the town ordered the ringing of the bell at that hour.

It Beats a Horse-chestnut.—A reporter of the Boston *Record* says that he met an old friend of his who used to be crippled with rheumatism. Upon expressing surprise at seeing him so well and free from pain, the man replied that his cure was due to his carrying an old electric light carbon which one of the lamp men had thrown into the street. He claimed that there was enough electricity left in the old carbon to "knock the rheumatiz higher'n a kite."

Life Insurance Examinations.—One of the London life insurance companies has given up medical examinations, and insures the applicant on his own certificate of health, the sole condition being that the amount of the policy shall not be paid if the insured dies within five years. In that case his heirs receive only the amount that has been paid out in premiums with interest.

The Use of Narcotics by Women.—Dr. Norman Kerr writes as follows in *Woman*, upon the constantly increasing use of narcotics by women: Alcohol is the narcotic most frequently used. But I could give you a formidable list of narcotics which women in all ranks of society are daily using: Chloral, chlorodyne, ether, chloroform (less used by women here than in America), sal volatile, eau de Cologne, and so on. I have known ladies addicted to alcohol drink three bottles of brandy a day. A bottle a day is by no means an uncommon quantity. I have had patients who had habituated themselves to two ounces (960 grains) of chloral as their daily allowance. Twenty grains of chloral, I may say, is a full medicinal dose. I have treated patients who have been in the habit of swallowing eight ounces of chlorodyne a day; and I have known ladies who could take a pint of chlorodyne in the twenty-four hours. Both tea and coffee are used in excess. I found a patient insensible in her room one day who had drank nothing but tea. But she had consumed a pound of tea in the day. Tobacco, in the form of cigars as well as of cigarettes, is constantly resorted to. Thirty cigarettes a day has been the allowance of some of my patients.

The Death of an Old Woman.—There died recently in Vienna a woman who was commonly reputed to be over one hundred and fourteen years of age. Her name was Magdalena Panza, and she had a daughter aged seventy-four still living, six other children which had been born to her having died. She had never been seriously ill until her hundredth year, at which time she had a severe fall and sustained some injuries, from which, however, she promptly recovered.

The Size of French Families.—A law was passed not long ago in France, giving certain privileges to the fathers of more than seven children. An inquiry having been made to determine who were to benefit by the provisions of the law, it was found, according to *Lyon Médical*, that in France at present there are 2,000,000 households in which there has been no child; 2,500,000 in which there was one child; 2,300,000, two children; 1,500,000, three; about 1,000,000, four; 550,000, five; 330,000, six, and 200,000 seven or more.

The Czar again Accused.—The Czar of Russia must be in a bad way if all that is said of him is true. It has been reported that he is a profligate of the worst type, a confirmed drunkard, an irresponsible lunatic, and now comes the statement from a French paper that he is a morphine fiend, using about fifteen grains of the drug by hypodermic injection every day.

The Physician not his own Druggist.—A bill has been introduced into the Ohio legislature forbidding a physician from administering any medicine whatever to his patients except in case of emergency. We hope that it is accompanied by another bill forbidding counter-prescribing by pharmacists.

Of Interest to Volapükists.—Dr. Mies, of Bonn, Germany, proposes to publish, in Volapük, an article on the size and weight of new-born children, and he requests all who may possess any information on this subject, to send it to him, and in return he will express his grateful appreciation in the choicest and most classical Volapük.

Dr. T. T. Slaughter, of Madison County, Va., now in his eighty-sixth year, has practised medicine for over sixty years, having taken his degree from the University of Pennsylvania, in 1825.

Danger in the Kid Glove.—A lady in Vienna was poisoned not long ago by a new pair of kid gloves which she had worn to a ball. It was ascertained that the skin was obtained from an animal that had died of the rinderpest.

The Cookery of the Poor.—A faculty of social science has, it is stated, been instituted at the University of Brussels, and Professor Berger, a Belgian authority in chemistry, has given a course of lectures on alimentary chemistry. In the first of them he came to the academic conclusion that it was possible to determine with precision the quantity of nutritive elements indispensable for the reparation of the power of a working man, and consequently the amount of money necessary for purchasing this quantity, and that, therefore, when the other primary wants of a working man were determined in the same way, the minimum of salary could be fixed with scientific accuracy. Questions of taste, digestibility, and prejudice are, however, apt to be ignored in calculations of this kind; so that, although of value as a basis of information, they are far from having the practical use which their authors ascribe to them. The knowledge of the housewife and of the cook, and a familiar acquaintance with the habits and surroundings and tastes of the laboring classes, are necessary to give reality to such calculations. An excellent example of what may be done in this way is furnished in the able and interesting chapters on the subject in the popular little handbook of domestic economy issued by Messrs. Cassell & Co., and largely used in board schools, entitled "The Making of the Home," written by Mrs. Barnett, of St. Jude's, Whitechapel. The same subject is treated with great technical knowledge and power of sympathetic feeling for the poor in her chapter on "Our National Defences," in the joint essays by herself and the Rev. S. A. Barnett, in the well-known collection of essays entitled "Practicable Socialism." The subject is one in which medical men, skilled as they are in the physiology of food, and accustomed to deal with the poor both in family life and in public institutions, might give great aid. That which our working classes greatly need is instruction in the art of braising, or slowly stewing at a low heat, combinations of meat scraps and of vegetables. Anything more toothsome and nutritious than the vintagers' *pot au feu*, which I lately tasted in the Medoc during the gathering of the grapes, cannot well be imagined. It was so delicious that a supply of it was ordered into the Château for midday lunch, and it was voted by acclamation worthy of a *cordon bleu*. It was made with leg of beef, onions, carrots, cabbage, and the like, and poured smoking into bowls over slices of thin bread. What a lesson it conveyed to our managers of soup-kitchens, and what a meal for our harvesters!—*The British Medical Journal.*

Primary Tubercular Disease of the Eye.—Like all comparatively rare diseases, cases of primary intraocular tubercle may give rise to considerable doubt in the minds of those under whose care they are, both as regards diagnosis and treatment. In certain instances it is next to impossible to distinguish between tubercular and syphilitic nodular iritis; yet in reference to the adoption of active treatment a correct diagnosis is all important. Such doubtful cases have been described on several occasions as granuloma of the iris, a name which is said by some authors to signify that the disease is of syphilitic origin, while others hold that it is tubercular. At the best it probably means that our knowledge of such cases is not yet complete. The doubts which arise regarding treatment chiefly concern operative measures. If the disease be tubercular, should the eye be excised, in the hope of removing a centre of infection, and thus preventing general tuberculosis? If syphilitic in nature, active antisyphilitic treatment is indicated, and these measures would but doubtfully conduce to the cure of tubercle. The records of cases seem to point to enucleation as the best treatment for primary intraocular tubercle; on the other hand, in a certain number of cases recovery has ensued from disease which had all the clinical characters of tubercular iritis. One point seems fairly well established, viz., that if any operation is undertaken it should be removal of the entire globe; iridectomy, performed with the intention of removing the diseased portion of iris, has been almost uniformly unsuccessful.—*The British Medical Journal.*

THE RELATION OF ERRORS OF REFRACTION AND INSUFFICIENCY OF THE OCULAR MUSCLES TO FUNCTIONAL DISEASES OF THE NERVOUS SYSTEM.[1]

By D. B. ST. JOHN ROOSA, M.D., LL.D.,

PROFESSOR OF DISEASES OF THE EYE AND EAR IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL; SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL.

About thirty-three years ago, when Donders began to make known in Graefe's *Archives* his great discovery, the fruit of some years of labor in the light of the ophthalmoscope, that asthenopia was chiefly the result of an error of refraction whose nature he had himself clearly demonstrated, he found the medical profession engaged in proving that it was due to defective action of the external muscles of the eye. It was then taught by the highest authorities, that the cause of asthenopia was to be sought in a spasmodic contraction of some of the ocular muscles. There were practitioners, as Donders remarked, who had the courage to divide these muscles for asthenopia, and he proceeds to say, that this is a melancholy page in the history of operative surgery.[2] But these practitioners are to be forgiven; they had gone as far as our knowledge of physiology would allow. The source of the accommodation of the eye for vision at different distances, had not then been discovered, nor had its mechanism been explained. The retina, however, had been abandoned as the *fons et origo mali*, and we were nearing a solution, when the ills of asthenopia were ascribed to muscular action and not to the retina, even if the wrong muscles were attacked.

Any proper discussion of so-called ocular reflexes, resulting from strain of the eye, must begin with a definition of asthenopia. Perhaps that of Donders is the best.

"The eye has a perfectly normal appearance, its movements are undisturbed. The convergence of the visual lines presents no difficulty. The power of vision is usually acute, and nevertheless in reading, writing or other close work, especially by artificial light, or in gloomy places, the objects after a short time become indistinct and confused, and a feeling of tension comes on, especially above the eyes, necessitating the suspension of work. The person so affected now often involuntarily closes his eyes, and rubs his hands over the forehead and eyelids. After some moments' rest he once more sees distinctly, but the same phenomena are again developed more rapidly than before. The longer the rest has lasted, the longer can he now continue his work."[3]

But Donders went no further than to say that the asthenopia thus described, depended upon one of two causes: either upon a short eyeball, hypermetropia; or upon some constitutional disturbance, such as occurs in a marked way in paralysis from diphtheria, and prevents the use of the muscles of accommodation. This latter form, has been often confounded with that which Donders said was caused by hypermetropia. It may exist coincidentally with hypermetropia, usually of a low degree, or with weakness of ocular muscles, and it is an accommodative asthenopia. But an error of refraction is not at all the cause of it. Exhaustion of the nervous system, hereditary or acquired, from various sources, is at the bottom of this kind of asthenopia. It often depends upon incurable general conditions. But true accommodative asthenopia is curable by means of correcting glasses. The former variety is sometimes called American asthenopia. It is more common in our country than in France, perhaps than in Germany and England. At least one Frenchman thinks it is more frequent in New York than in Paris, because New York men and women are not so well nourished by good and well-cooked food and sound red wine, as are the corresponding class in Paris. I am not prepared to dispute this opinion.

It is important to bear in mind this distinction between accommodative asthenopia occurring in neurasthenics, women with uterine disease, malarial subjects, those recovering from typhoid fever, and so forth, who, at the same time, like the rest of the world, have slight refractive errors and insufficiencies, and pure accommodative asthenopia in healthy subjects, caused either by high degrees of hypermetropia, astigmatism of even moderate degree, great weakness of the internal recti, unequal refraction of the two eyes, or the like.

Although Donders was the discoverer of the nature and the cause of asthenopia, he had no idea of its frequency. While he recognized the fact that headaches, melancholy sensations, and a long train of evil symptoms might result from asthenopia, he did not know how frequently these symptoms were caused by ocular fatigue. In his time the public were somewhat discouraged in getting medical aid for the relief of these symptoms, and readily gave up the use of their eyes for near work, and turned to agriculture or idleness, as a palliative for what could not be cured.

Donders found in a shortened eyeball the chief cause for asthenopia; as he says, "hypermetropia is usually at the bottom of asthenopia." If he had known as much of the effects of astigmatism as he and Knapp had shown us of its nature, he would have said hypermetropia *and* astigmatism.

At this very time, Graefe was in the midst of his investigations of muscular asthenopia. Donders was careful to describe muscular asthenopia also. He believed that it depended chiefly on insufficiency of the internal recti muscles. Up to this day Donders's classification has been pretty generally accepted, and all writers speak of accommodative and muscular asthenopia. But Donders underrated the importance of astigmatism in producing asthenopia, and, scientific and wise as he was, he was so overshadowed by the great genius and authority of the pioneer in modern ophthalmology, Graefe, that he laid undue stress upon muscular asthenopia, although his work removed a great deal of what I believe was not only then, but is now, a fictitious importance ascribed to this latter condition. Even then, he calls attention in an uncertain way to the important fact that errors of refraction were practically fixed conditions, while muscular insufficiency must be as variable in the eyeball as in the leg or hand. But Donders's work stopped much of the cutting of external ocular muscles and narrowed the field of muscular asthenopia. In reading the work of the great Dutch physiologist in the light of subsequent years, it seems as if his courtesy restrained him from speaking his full mind about the *ignis fatuus* of asthenopia dependent upon insufficiencies of ocular muscles. Graefe admitted at a very early stage, that the combined action of the recti interni for accommodation for the near point is extremely different under physiological conditions in different persons. He might have added in the same person.[1]

Matters as to asthenopia, both in the old and new world, rested for a number of years about where Donders left them. Although he speaks of gloomy feelings being changed to those of hope and exuberance, in consequence of a relief from asthenopia by wearing glasses, and adduces several graphic cases of this kind, he did not fully appreciate the great relief that the practice of ophthalmology in the light of his discovery of the nature of hypermetropia and astigmatism, was to bring to thousands upon thousands of suffering men and women, much less did he dream that the origin of nearly every form of disease of the nervous system was to be found in an error of refraction or an insufficiency of ocular muscles. It was reserved for America to claim that not only asthenopic affections were due to errors of refraction and accommodation and muscular insufficiencies, but, to quote the exact words of the author, "difficulties attending the functions of accommodating and of adjusting the eyes in the act of vision, or irritations arising from the nerves involved in the processes, are among the most prolific sources of nervous disturbances, and more frequently than other conditions constitute a neuropathic tendency." [1]

But the definition of asthenopia became more comprehensive, the resulting headaches and twitching of the lids were more fully described and recognized by ophthalmologists everywhere. Blepharitis and styes and tarsal tumors, were added to the list of these consequences.[2] But until about 1874 the evil consequences of uncorrected errors of refraction, were supposed to be limited to the area directly in connection with the eyeball. There was no claim that asthenopia, except by mental depression, extended beyond this region in its evil effects.

At first it was claimed that chorea as well as epilepsy, although sometimes dependent upon organic lesions, were generally functional nervous affections, under which head they are classed. And even now Dr. Stevens says:

"The anatomical lesions of the brain or of the cord are sometimes coincident with chronic chorea it is true, but that there is necessary or causative relation between the two conditions has not yet been shown. Indeed, it is much more probable that the anatomical lesions of the brain and cord are among the results of chorea, or of the irritation causing it, and that they are not in any respect the original sources of irritation." [3]

Of late this claim has been somewhat modified, and great pains is now taken to state that, when epilepsy and chorea are mentioned, there must be careful discrimination between functional and organic chorea and epilepsy,[4] and that only the former are proper subjects for operation. In the early papers we hear very little, if anything, of the differences between chorea and epilepsy dependent upon organic causes, and the functional forms. Dr. A. L. Ranney, who is well known as a disciple of the promulgator of the doctrine of the ocular origin of nervous disease, even now speaks of chorea as always a functional nervous disturbance. He says that it is doubtful to his mind, if any changes exist in the brain or spinal cord with chorea.[5] The same author admits that epilepsy may have an organic cause. But it is apparent that he believes that this is exceptionally true and that epilepsy is also a functional disease.[6]

When chorea, epilepsy, and insanity were all classed under the head of functional nervous disease, it was at first claimed that hypermetropia was the chief influence in the production of these functional nervous diseases. It was then deemed sufficient to correct the hypermetropia or the astigmatism. In a paper read before this Academy,[7] it is plainly stated by Dr. Stevens, that "chorea is a functional disturbance of the nervous system, which may give rise to organic lesions, and which arises from irritation dependent upon anomalous refraction of the eye, and in a very large proportion of cases to hypermetropia." But of late years, say from 1886 or 1887, the muscles are said to play the chief part in causing the functional diseases, and operations upon them are necessary for the cure. A new nomenclature has been promulgated for the purpose of defining muscular insufficiencies, and operations upon these muscles have largely supplemented or taken the place of the correction of errors of refraction. Thus we have returned in a circle to the position in which Donders found Graefe, and the ophthalmologists preceding him. Asthenopia, from which nervous diseases of all kinds are now said to result, is chiefly dependent upon muscular insufficiencies and is generally to be relieved by operations upon these muscles.

It now becomes necessary to make rather a long quotation, in order to show what is claimed will follow from an adoption of the general principle, that functional nervous diseases depend chiefly upon faulty action of the eye.

"I think it not unreasonable to look for the future advance in medical practice along two great lines. That advance along one of these lines was begun when Jenner, recognizing the fact that the human subject may be made sterile to the development of certain organisms when once it has been preoccupied by the presence of the same or a similar class of organisms, introduced vaccination as a preventive of one of the greatest scourges of the race. In our day an army of investigators, well trained and well equipped, is exploring the realms of the minute in search of the micro-organisms which, in their invasions in swarming myriads within the human body, threaten to destroy it by their devastations. It is not impossible that against the inroads of the various organisms whose incursions constitute typhoid and typhus, scarlet fever and measles, cholera and yellow fever, barriers may be erected which shall in large measure protect against the class of maladies which now destroys so large a proportion of the population of the world. The advances which have already been made along that line are, doubtless, but the earnest of that which is to come.

"Along the other line we may look for as great achievements. The class of maladies which has been during all time relegated to the tender mercies of fetichism and superstitious notions of cures by drugs having no relations to the origin or the nature of the disorders themselves, will ere long be regarded as irregular phenomena resulting from well-defined causes of irritation, which causes must be sought for principally in the direction of difficulties in the performance of necessary functions. With the removal of such difficulties we may look with confident expectation to the cessation of the peculiar irregularity which constitutes the special form of nervous disease. Through such means we may reasonably expect that the great class of functional nervous troubles, of which epilepsy and insanity, neuralgia and hysteria may be regarded as representatives, will be nearly as effectually guarded against as is small-pox by vaccination." [1]

The quotation just made, is an extract from the paper that led to the formation of a commission of experts, to investigate the subject of the cure of nervous diseases by glasses and tenotomies.

It was supposed at one time by some of the writers who have discussed this subject in the medical journals, that insufficiencies of the ocular muscles, except of the interni, were never discussed until the discoveries of 1876 and 1880; but reference to the writings of Graefe [2] the nephew, Loring, and others, show that this was incorrect, and that even latent insufficiencies of all the muscles, were recognized years before this.

It was Alfred Graefe also who clearly laid down the rule,

lately so often ignored, that errors of refraction and accommodation should be corrected before noting muscular insufficiencies, and this for the simple reason that muscular insufficiencies are often caused by uncorrected errors of refraction.

These novel views as to the causation of functional nervous diseases, have now been subjected to years of very thorough investigation, accompanied, on this side of the water especially, with much acrimonious disputation. In Europe they have excited little attention. A learned commission has sat upon the whole subject, and, although its report is unanimous, and bears, on the whole, rather heavily against the value of the discovery of a great principle of cause and cure, it cannot be said to have closed the subject, for in the discussion that followed the report of the commission, one of its members seems not to be quite certain of the propriety of an adverse report. In his remarks he lays great stress upon the delicate instruments and manipulations which have characterized these curative operations, and he also said that "not being a neurologist, he did not feel competent to judge of the therapeutic effect of these operations."

From the editorial remarks of a journal conducted by another member of the commission, we may fairly conclude that he also did not fully agree with what was supposed to be a unanimous report. A leader in this journal says: "Now, what does this prove, and does it prove anything? It would seem to prove that Dr. Stevens's method is a therapeutic measure valuable as an adjunct, and that in certain cases where toxic medication is unwise, it constitutes one more means of alleviating suffering." [1]

The commission, however, unanimously expressed the opinion that the method of Dr. Stevens does not afford a sufficient degree of relief to patients suffering from chorea or epilepsy to warrant its adoption or recommendation to the Neurological Society, as a means of cure, or as the sole therapeutic measure." [2] In the debate that followed among the neurologists, there was a minority which did not fully agree with the report.

It is evident, that there is still such a state of unsettledness in the minds of quite a fraction of the medical profession upon this subject, as to justify further discussion. For this reason I have accepted the invitation of the President of the Academy, to present my views upon peripheric irritation as a cause of disease, especially with reference to irritations of the eye.

The basis of argument by which chorea and epilepsy were considered to be due to errors of refraction and accommodation, has, in my opinion, been long since shown to be entirely fallacious, although in the monograph upon this subject from which I have already quoted, great stress is laid upon these tables. The following is an example of one of them:

Of 118 cases of chorea,[3] 78 are said to have been hypermetropic; 13 had hypermetropic astigmatism; 5 had mixed astigmatism; 6 were myopic, and 11 had myopic astigmatism.

This table, and also the similar tables that are furnished with reference *to errors of refraction* in epilepsy and migraine, are of no more importance than if they stated that of one hundred and eighteen persons suffering from measles or a broken thigh, such a proportion were hypermetropic and so forth. It has been shown by myself,[4] by Ely,[5] in his "Examination of the Newly Born" (correcting the observations of Jaeger, who had supposed the infantile eye to be myopic), by Randall[6] and others, that only a very small proportion of adults or infants, say seven per cent., have absolutely emmetropic eyes. We did not know this when Donders made his discoveries, although Donders knew that a low degree of hypermetropia was exceedingly common, and he did not reckon such as likely to cause asthenopia. Indeed, he did not consider it to be an abnormal condition.

Stimulated by the claim made in 1876, which I have quoted, that functional diseases of the nervous system were due to hypermetropia more than to any other one cause, my investigations of adults who had never suffered from asthenopia and whose eyes were placed under the full influence of atropia, were first made in 1877. They were followed by others, and all agree in showing that, excluding the myopic, nearly all the world is hypermetropic. If all the world be myopic or hypermetropic, how can it be in reason claimed that these conditions in themselves cause the functional diseases of the nervous system? At least the advocates of such a doctrine would be obliged to admit that other causes must act in conjunction, with these deviations from an almost unknown normal standard, to produce any grave disease.

It was demonstrated by these papers, and by C. S. Bull, that people could be perfectly well and have all the errors of refraction and accommodation that were said to cause chorea and epilepsy. These tables of errors of refraction occurring in epilepsy and chorea were thus stripped of all their value, and the arguments resting upon them fell with them. Without fairly admitting this, the tables were still published, but the argument was now changed to meet the new facts confronting the new theory. In a paper read in 1880[1] attention was called to the fact, said to have been discovered in 1876, that insufficiencies of the straight muscles of the eye, by causing want of coordinate action, might cause nervous disturbance in the same manner as, or in conjunction with, refractive lesions. Then the formula was altered, and now functional nervous diseases are dependent upon anomalous conditions of the refraction and accommodation, *or upon imperfect action of the muscles of the organ*, "more than any other causes combined."

It seems to have been thus tacitly conceded, that errors of refraction alone, are not the chief source of functional nervous disease, but this was not said, although the argument was transferred to the muscles of the eye, to muscular insufficiencies. It is the doctrine that nervous disease is caused by these insufficiencies, and is relieved by ocular tenotomies that I now wish to combat.

Before I follow this doctrine of the dependence of neuroses upon want of ocular muscular equilibrium, to its legitimate ending by statistics showing how few people have such a muscular equilibrium, I will read the main outlines of a table which shows what people who come to an oculist for glasses actually suffer from, and how few of them have anything but accommodative asthenopia. Considering the assertion that, "more than all other causes combined," epilepsy, chorea, and other functional nervous diseases depend upon conditions of the eye, is it not remarkable that so few of them consult an ordinary oculist? These tables were prepared for me from my private case-books by Dr. Frank N. Lewis.

A table showing the symptoms complained of by patients, who came to have glasses fitted.

Asthenopia	1,445
Not seeing well in the distance	428
No history[2]	325
Blepharitis, styes, chalazia, etc.	265
Headaches	213
Not seeing well for near work	211
Glasses unsatisfactory	191
Conjunctival irritation, trachoma	178
Pain in the eyes	149
Diplopia	43
Muscæ	39
Lachrymation	31
Sent by a neurologist to learn the refraction	20
Dizziness	15
Twitching of the lids	11
Photophobia	5
Blur before one eye	5

Orbital neuralgia	1	..	..	..	..	..	..	..
Dilated pupil	..	..	1	..	..	..	..	..

These patients came to me, not because they had general nervous disease, but because they had symptoms beginning plainly in the eye, or in its appendages or adjacent to them. There I think may be found a true guide in diagnosis. It will be remembered, that in accordance with the theory that the causes of chorea and epilepsy and so forth, are to be found in the ocular refraction or muscles, it is not necessary that the eye or its appendages should manifest any symptoms at all. The condition of the eye is to be revealed by skilled observations as to the refraction, and delicate tests as to muscular equilibrium. These causative conditions may be completely concealed until thus demonstrated. Patients who never knew that they had an ocular symptom, are told that all their troubles proceed from their accommodative and visual apparatus. This is not in accordance with the usual condition of things. A splinter in the tissue, a foreign body of any kind in any part of the body, whatever reflex disturbance it may give rise to, will usually give local symptoms also, and thus call attention to its origin. In this, I do not believe the eye, ear, nose, or throat are any exceptions. If we have actual reflex disturbances of the general system from the eye, besides those disturbances, asthenopia in one of its many forms will show itself. I do not believe that a refractive error or a want of muscular equilibrium that causes no local disturbance, will, except in highly exceptional cases, if ever, cause any constitutional affection.

It is not possible in such a paper as this, to give even the outlines of the individual cases that demonstrate in detail, and unanswerably, the failure of this theory to account for the origin of nervous diseases. If *falsus in uno, falsus in omnibus*, be good logic, every oculist's case-book will overthrow the doctrine of the ocular origin of nervous disease. Chorea has been entirely recovered from years before any correction of an error of refraction occurred. In other instances, one eye has never been used with the other, and yet most active careers, requiring most profound, patient, and exacting mental labor have been successfully carried on, marred only by slight asthenopia. Again, vertigo said to depend upon want of co-ordination of the ciliary and recti muscles, has been recovered from, while the want of co-ordination remained just the same. Every oculist of wide experience sees many such cases. They utterly destroy the theory that any discovery has been made of wide adaptation, which places refractive defects at the basis of general disease of the nervous system.

I could speak also of the essays upon this theme, which gravely fill pages of print with the most primary details as to accommodation and tests of vision, details to be found in every text-book upon diseases of the eye, but which are described as being something new in connection with the great discovery of ocular conditions "more than all their causes combined" as giving rise to nervous disease. I might also mention the anxiety produced in the laity about their eyes, which has caused presbyopes who have no accommodation of any disturbing kind, to submit to disabling of their vision with atropine for two weeks, in order finally to get a pair of glasses, which any oculist would prescribe, and correctly prescribe, in fifteen minutes by the clock. If this dictum which we are discussing be true, most physicians should become oculists. Very little other knowledge than how to test the refraction and the muscles, and how to cut the latter will be needed, if the predictions as to the importance of this discovery are fulfilled.[1]

It having been pretty thoroughly established that errors of refraction among well people, are the rule and not the exception, the next thing naturally is to determine how many well people—that is, well as to asthenopia and nervous symptoms—have what is called muscular equilibrium, or, to use a modern nomenclature, have *orthophoria*, or parallel eyes.

I have recently investigated these conditions of muscles, which are said to be the prominent, if not the chief, factors in causing neuropathic conditions, and I present the table herewith. The investigations were made by one of my staff, Dr. Deynard, of the Manhattan Eye and Ear Hospital, with the phorometer, with strict attention to the details laid down in the recent writings upon this subject. I personally have never examined the cases. Dr. Deynard has been perfectly untrammelled in his investigations.

One hundred and three persons who did not have any trouble with their eyes that they knew of, who read and wrote and sewed, without headaches or asthenopia, who had no vertigo, chorea, epilepsy, hystero-epilepsy, or insanity, were selected as objects for testing. Eighty-three

[1] The views of those who believe that migraine is always to be ascribed to ocular defects, if those defects are found, are well presented in a recent lecture by Dr. Seguin (New York Medical Journal, April 5, 1890). He says: "The proportion of subjects of migraine who have ocular defects is amazing; very nearly all have either errors of refraction or muscular insufficiency, or both combined. In 1882, I received from Dr. G. C. Savage, of Jackson, Tenn., a very courteous letter challenging me to furnish a case of migraine in a person with normal eyes. I have not yet met with one, though I have been told of two or three by oculists in whom I have confidence. Of course the statement as to the invariable concomitance of eye-faults with migraine presupposes that the patients have been examined thoroughly —*i.e.*, under the full effects of atropine for refractive errors, and by Stevens's method for muscular insufficiency. I regret to say that there are still oculists of good standing who examine the eyes of headache cases in the most careless way, ordering glasses without having used atropine, and ignoring the muscles altogether. This has happened under my observation in New York within six months."

All this argument falls to the ground, when we learn that thousands of people have all these defects and yet have no migraine. I have also seen many persons with migraine who were no better after a careful correction of astigmatism and muscular insufficiencies, although some are much relieved by glasses, especially cylindric glasses. Dr. Seguin adds: "Another argument in favor of the ocular origin of migraine is that other remarkable fact, that in many persons of both sexes the attacks diminish and cease between the ages of forty and fifty years. It is at this period that the power of accommodation becomes exhausted and a large part of the unconscious strain which has been going on from early youth is removed."

This cannot be the explanation, for it is just after presbyopia comes on, that astigmatism often becomes very troublesome, especially astigmatism of a moderate degree. I know of many cases where asthenopia, blepharitis, and so forth, first appeared when glasses were needed for fine print, and the spherical ones proved insufficient. The cessation of attacks of migraine can hardly, in the light of this fact, be due to the let up in the accommodation incident to middle life. Dr. Seguin falls into the error now so common of ascribing headaches and so forth to the eye, simply because errors of refraction are coincident with the neurosis.

Many neurologists have unfortunately not kept up with recent accessible ophthalmological literature. They are working upon lines that were given up by oculists ever since the actual percentage of ametropia was discovered.

were aural patients attending the Manhattan Eye and Ear Hospital; 6 were friends who came with them; 11 were physicians; 1 was a music teacher; 1 was a servant, and 1 a detective. Seventeen, or sixteen per cent., were found to have muscular equilibrium; 84, or eighty-one per cent., had a want of muscular equilibrium, so-called heterophoria; of these 27, or twenty-six per cent., had deviation outward, exophoria, insufficiency of the interni, and 74, or seventy one per cent., exophoria in accommodation; 16, or fifteen per cent., had deviation inward or esophoria, insufficiency of the externi; 7 had esophoria in accommodation; 11, or ten per cent., had hyperphoria, a tendency of the right or left visual line upward; 24 had hyperphoria in accommodation. A re-examination of five of these patients all showed a change in the muscular examination from that found at first. This is an important observation, since it proves, as asserted by Starr and others, that the muscular power in the same eyes is not fixed, but variable.

Hence it is seen that any series of cases founded upon certain ocular insufficiencies, cannot be said to be proven when the existence of these insufficiencies is shown, for they may exist in connection with entirely healthy nervous systems just as errors of refraction may. The value of observations founded on such tables is now no more than of those founded on errors of refraction. Not only does all the world have faulty refraction, but very few people possess equilibrium of the ocular muscles.

The capacity for great intellectual work with great muscular insufficiencies, is well shown by the following extract from a letter relative to the perception of distance by Sir William Rowan Hamilton, Astronomer Royal of Ireland,[1] printed in his biography: "Though I habitually see a double universe, yet a marked improvement has taken place within the last few weeks in my power of seeing single. This I attribute to my having lately, for the first time in my life, bought a stereoscope and used it at leisure. A friend within a few minutes' walk of me has long had a stereoscope apparatus, but years elapsed before I could catch the effect at all. With each eye separately I saw a good relief, but it is 'two years ago' that I first was able to see that tertium quid which is the true result of the stereoscope, and certainly it greatly astonished me" (written by Hamilton to De Morgan at fifty-eight).

Hamilton also states that on the evidence of his friends he did not squint, and his photograph shows that he did not do so in any marked degree.

The study of the causation of disease is certainly a very important one, but it is almost as puzzling at times as the theological problem of the origin of evil in the world. Yet some things we do know. If a man lives in a malarial swamp and intermittent fever attacks him, or if he drinks water polluted with typhoid bacilli and gets typhoid fever, or if he is exposed to a case of small-pox and breaks out with this disease, or if after prolonged exposure to wetting he is attacked with acute rheumatism, we have no difficulty in saying as to where the cause of his disease is to be found. But no philosopher will conclude that cholera is caused by insufficiency of the ocular muscles, because a large proportion of those seized with this disease, as is certainly true, have such an insufficiency. The true philosopher will recognize in nervous maladies a series of causes acting together, and at the bottom of them all, in this country at least, will be found that illy defined condition of which we know so little, but of which we shall know more, called, nervous exhaustion.

To go back to errors of refraction for a moment. Another fact should be noted in this discussion. Contrary to what is stated by Ranney, hypermetropia is constantly outgrown in the development of the eyeball, as every ophthalmologist knows. A hypermetropic eye may even become myopic. Glasses needed at twelve and fourteen are discarded without asthenopia at twenty, and so forth.

The inconvenience of uncorrected errors of refraction, especially of high degrees of hypermetropia, and of even inconsiderable degrees of astigmatism, can hardly be overestimated with reference to their influence upon the head and the face, and upon the spirits of some patients, but their influence generally seems to stop there, except in very rare cases in neurotic subjects.

It is not an uncommon experience in malaria and after recovery from typhoid fever, to find accommodative asthenopia, which is only relieved when quinine has cured the malaria, and time and hygiene have restored the shattered nervous system of the sufferer from the *fièvre nerveuse*.

Those who believed that in the eye, "more than in all other causes combined," are to be found the cause of functional nervous disease, would have been now on surer ground if they had stood by the first declaration, that errors of refraction were the cause, and not taken refuge in want of muscular equilibrium.

A great deal of muscular insufficiency depends upon uncorrected astigmatism. Alfred Graefe and Loring were right. We can say very little as to what constitutes a muscular insufficiency until the refraction, and I say especially the astigmatism, be corrected. A thorough use of atropia, or better still, an examination by Javal's ophthalmometer, will often cause us to correct a troublesome insufficiency by cylindric glasses and not by prisms, much less by a tenotomy.

There is a large class of neurotic patients who may or may not have high degrees of errors of refraction, generally, however, they have only low degrees of hyperopia or hyperopic astigmatism, whose accommodative asthenopia, like their headaches, depend upon hereditary faults and predispositions. These neurotic families seek, now in one panacea and now in another, cure they will never get. Palliation is all there is for them. Neurotic they are born and neurotic they will die, although for a time one set of symptoms may be transferred to another. Like Dr. Loring's case which I have before alluded to in this Academy, "their eyes have got all right, but it has gone to the stomach." I know of a neurotic family where one member has had a dozen operations upon his eyes, but he is as neurotic as ever. Another has had all her troubles transferred from her ovaries to her eyes, by excessive attention to them. She goes about discoursing upon advancements and divisions of recti muscles; but sure that without her oculists she would have died. A third member, with myopic astigmatism in one eye and myopia in the other, and the difficulties of presbyopia coming on, is nearly harassed out of his domestic peace by the urgent desires of his more fortunate relatives that he should seek relief in ocular tenotomies. Other patients, who have never suffered from asthenopia until they began to undergo treatment for nervous disease by tenotomies, wander over the earth seeking to have a double vision removed, of which they once knew nothing, and yet complaint is made by the author of the doctrine I am combating that, after months, and even years of attendance and several tenotomies,[1] patients are withdrawn from treatment while defects of great importance are known to exist, which by continuous effort might be removed.

Donders' argument, that in errors of refraction and not in muscular insufficiencies would be found the chief cause of asthenopia, was not put very plainly, but I undertake to say that not in the muscles but in the eyeball, in the refraction, the sources of ocular reflexes are to be found, such as occasionally exist, just as a foreign body in the ear may occasionally cause epilepsy, or a decayed tooth cause spasm of accommodation. The condition of the muscles is unstable, as has been pointed out; and, as my tables show, what is a man's power in his ocular muscles to-day, may be another to-morrow.

These cases of epilepsy and chorea dependent upon peripheric irritation are entirely exceptional, while asthenopia is real and common. We have no reason to

[1] I am indebted to my friend Dr. Dennet for this quotation from the life of this eminent savant.

[1] New York Medical Journal, April 16, 1887, p. 427.

hope, from anything that has yet been shown, that there is any large class of functional constitutional nervous diseases caused by peripheric troubles, and, as I have said, whatever there are, are to be sought for not in the muscles but in the eyeball. The conclusions to which I have come, as a result of twenty-six years of work in ophthalmology, with a careful consideration of the writings and works of others, including those who believe that functional nervous disease is due to the eye "more than to all other causes combined," are as follows:

First. The eyeball of the human race is very rarely in what might be defined as an emmetropic condition.

Second. Perfect equilibrium of the ocular muscles is by no means a common condition, even among persons of sound health and without asthenopia.

Third. Defects in these two states by no means necessarily produce even local disturbances, such as are comprehended under the term of asthenopia, inflammation of the edges of the lids, and so forth, although high degrees of hypermetropia, moderate degrees of astigmatism, and all cases of mixed astigmatism are apt to do so, sooner or later.

Fourth. Asthenopia depends chiefly upon two sets of causes—nervous exhaustion and uncorrected errors of refraction.

Fifth. In estimating the influence of these defects great stress should be laid upon the general condition, and the line sharply drawn between asthenopia due to exhaustion and that to faulty refraction.

Sixth. Nothing has been added essentially to Donders' discovery of the fundamental cause of accommodative asthenopia, except that astigmatism forms a more important factor in its etiology, muscular asthenopia falls into the background, while the definition of asthenopia has been much amplified by ophthalmologists.

Seventh. The origin of a considerable class of such diseases as chorea, epilepsy, and hystero-epilepsy has not been found in errors of refraction nor in insufficiencies of the muscles of the eyeball.

The observing general practitioner of our city is able to test the truth of this latter proposition as he looks among the neurotic families and individuals of his acquaintance, and observes whether or not the use of glasses and the performance of ocular tenotomies, are beginning to lessen the cases of chorea and epilepsy. Certainly a discovery which it was predicted would vie with those of Jenner and Lister has been proclaimed with sufficient fulness and clearness, and has been acted upon in an arena large enough to allow us by this time to judge whether or not it is an advance in rational and scientific therapeutics. I do not believe that it is, but I believe that the theory of the ocular origin of nervous disease, by distracting attention from the evident, and in some instances preventable causes of neuroses, has delayed our progress, and inflicted serious damage to the reputation of our profession for accurate observation and philosophical conclusions.

ON THE RELATIONS OF PERIPHERAL IRRITATION TO DISEASE, AS MANIFESTED IN THE THROAT AND NOSE.[1]

By BEVERLEY ROBINSON, M.D.,

NEW YORK.

During the past few years some eminent specialists in laryngology have attributed, as I believe, too much importance to irritations of the throat and nasal passages in the causation of disease. This position was almost to be expected when we reflect how prone the medical mind is to assign a prominent place to the particular organ whose diseases are familiar in the etiology of most human ailments. Add to this the fact that it has been proven that nasal obstructions are unquestionably, at times, the efficient factors in producing an outbreak of hay fever, or of asthma, and we have a sufficient reason to appreciate why surgical methods for the relief of these conditions became familiar and widespread. While we should see in this march evidence of progress and improvement, we should also be prepared to note what is evident exaggeration and excess.

Up to the time that Daly, Roe, Sajous, Bosworth, and others showed the nasal factor in the production of hay fever, this affection was integrally allied with a neurotic habit and the presence of pollen in the atmosphere. After the recognition of the fact that the nasal organ was frequently the seat of diseases which caused peripheral irritation, and thus led directly to hay fever, it was deemed essential to employ proper means to get rid of these diseases.

The affections referred to appeared to be of different kinds. Sometimes, in the opinion of careful observers, being of the nature of neuritis of the peripheral nerves of the pituitary membrane, as shown by the numerous areas of painful sensibility. Again, the turbinated bodies were in a state of notable hyperæmia or hypertrophy, or the septum was thickened or deflected, or polypi filled the nasal fossæ, or an adenoid vegetation clogged the post-nasal space. These were regarded as conditions which were strictly morbid and to be removed, with the legitimate hope of ameliorating or curing the hay fever. It soon became a routine practice to make use of the galvano-cautery, and in several successive sittings to cauterize all the attainable sensitive areas on the pituitary membrane. Or, if sensitive areas were not discovered, it was judicious to remove any existing obstructions to easy nasal respiration by means of the saw or trephine. Now, what has been the result? At first, and during a period of two to three years, it was not uncommon to read of the radical cure of hay fever being thus effected. Then a few accurate observers began to doubt these wonderful cures, and to notice that after a time the hay-fever victims were again sufferers, although in many instances their symptoms had been much ameliorated and they were hopeful for a time of a complete cure. Unfortunately, the cures were few when the cases were watched and followed up with impartial judgment. Theories were not wanting to account for the benefits which accrued to the patient from operation. Among the most seductive of these, I would refer to that of vaso-motor paresis of the large veins of the turbinated bodies, which caused a peculiar hyperæmia almost pathognomonic of the disease. This vaso-motor paresis is occasioned, as is stated, by the intra-nasal obstructions. When we remove the latter, we cure the former condition, which was a fruitful source of sneezing, nasal discharge, conjunctivitis, and cough. This interpretation is, I believe, in a few rare instances, true. In many it is in great part, if not entirely, erroneous. There are instances of hay fever in which cauterization, sawing, or trephining are wholly negative as regards their effects. Inasmuch as the operations have been undertaken frequently when it was simply the personal conviction of the operator which caused the nose to be occluded, and not the actual fact of it being so, we can appreciate that the patient was injured, if not relieved, by an unnecessary and useless operation.

Now, I do not desire for a moment to impugn the motives of such operators—I merely desire to direct attention to lack of judgment.

Admitted, they say, that hay fever depends upon a neurotic habit and a specific irritant, still the latter would not take effect if the nose were in a healthy condition, and they proceed to discover with absolute certainty this intra-nasal disease. Occasionally they are correct in their interpretation; the nose is diseased and requires surgical treatment. In many instances the morbid state of the nasal organ is merely a resultant of morbid processes situated elsewhere, and it will be remedied from this broad stand-point only by judicious medication.

Finally, there are instances in which the amelioration of the case may depend, in some degree at least, upon

[1] Read before the New York Academy of Medicine, March 20, 1890.

the proper local treatment of the nasal membrane; but this treatment should be that of soothing or altering the condition of the soft parts by suitable topical applications, and not the ablation or resection of portions of organs supposed to be diseased, when in reality they are healthy.

Much of what has been said as applicable to hay fever, is also applicable to hay asthma. Perennial asthma should now be considered. Can this disease—so difficult to treat successfully, so varied in its manifestations, of such different origin—be cured frequently by the removal of a nasal obstruction? Certainly and unhesitatingly I answer, no, it cannot. Peripheral irritation in the nose is without much doubt a predisposing cause of asthma in a certain proportion of cases; in a very moderate percentage should it be regarded as a direct and efficient cause of this disease. Asthma, as we know, may be occasioned by any number of conditions which are of the nature of peripheral irritations. A disordered stomach, a loaded rectum, a painful ovary, a decayed tooth may precipitate the attack. In like manner, an irritated or obstructed nose may produce this effect. I have seen many cases already in which the removal of mucous polypi or enlarged turbinated bodies from the nasal passages seemed to result in a cure for a time; but the cures were not permanent; the attacks of asthma returned sooner or later. It may be that they were ameliorated, that their intensity was diminished, and their frequency lessened; but the patient was not permanently cured.

In this connection I recall the circumstance of a distinguished practitioner of another city, who dined at my house some years ago, and who told me in confidence at the time of his great relief from asthmatic attacks by the extirpation of nasal mucous polypi, at the hands of a distinguished specialist of New York. Forty-eight hours later I was seated in an upper bed-room of the Fifth Avenue Hotel, caring for my confrère, who had had as bad an attack of asthma as I ever saw.

In a paper read by me before the American Climatological Society, in June, 1889, I stated that during the preceding year I had seen and treated about thirty cases of asthma due to different causes. Among these there were six in whom the asthma might be fairly ascribed to the existence of intra-nasal obstruction. Of these six cases, five were due to hypertrophy of the turbinated bodies in conjunction with more or less deviation and thickening of the nasal septum. The sixth case was one of nasal polypus. In all six cases operations on the nasal passages were undertaken. The nose was rendered pervious and the patients experienced much comfort as a result of the operations. As regards the effect on the asthma, it was noted that in four cases the asthma was at least temporarily improved. In two cases there was no marked relief. In the histories elsewhere reported in this paper there were many cases in which asthma existed, and yet at no time was there any appreciable nasal obstruction. Further, I have seen a large number of cases, several of which I have operated upon successfully, in which there was pronounced nasal occlusion, and at no time had there been the slightest tendency to asthma. Such cases, of course, can be readily explained by saying that the special neurotic element was lacking in them, and on this account the attack of asthma failed to occur. That may be true, but it was not always evident upon examination of the patients, and in some cases the nervous temperament was highly predominant.

These facts, I regret to say, are not wholly in accordance with the statement of Dr. Bosworth, who says that a large majority, if not all cases of asthma, are dependent upon some obstructive lesion in the nasal cavity. Against this we have the affirmation of Dr. Shurly, who writes that "daily experience overwhelmingly shows a very large number of cases of intra-nasal disease in persons of neurotic habit, with a very small proportion of cases of associated asthma."

"We are going much too far," says Dr. A. H. Smith, "when we seek to establish it as a rule that asthma is to be cured by operative procedures within the nose." As Dr. Daly affirms, it is unquestionably true, "that there is a certain proportion of cases of asthma that can be cured by putting the naso-pharynx in a healthful condition." And it is also true that some cases of asthma can be cured solely through the instrumentality of the cautery, the saw, the rongeur forceps, or the nasal trephine. These are the instances in which it is obvious that the permeability of the nasal passages is essential in order that the function of respiration may be carried on properly, and that the respiratory surface may be protected, and especially against the evil effects of constant or intermittent mouth-breathing. In the latter cases, the lungs do not receive a sufficient supply of air, and this fact may be corroborated by listening to the chest of one who alternately breathes through the mouth and the nose. Moreover, the nose is a filtering apparatus, besides providing the proper amount of moisture to the inspired current of air, and if it be interfered with, the foreign bodies floating in the atmosphere, instead of being arrested on its lubricated vibrissæ, penetrate directly into the lungs and cause, necessarily, irritation and distress.

Therefore, whenever an operation is required to render the nose permeable, and particularly when there is a tendency to, or confirmed asthma, it should not, if possible, be delayed or neglected.

Frequently, however, the nasal occlusion is due to a congestion of the pituitary membrane, which in these cases may be greatly diminished, or wholly relieved, by the medicinal agents which are employed for the purpose of restoring the freedom of the pulmonary circulation. Again, crusts, scabs, mucus, accumulate in the nasal passages at times, and promote an inflammatory process which can be temporarily relieved by a suitably-formulated spray. I have known the hyper-sensitiveness of the pituitary membrane to be greatly diminished at times by repeated applications of carbolic acid with glycerine and vaseline. Indeed, in this way I recall two cases of asthma of nasal origin in which I effected a temporary cure.

To show the difference of opinion in regard to the intra-nasal treatment of asthma, and particularly by cauterization, I would add that in the discussion following the reading of Lazarus' paper on this disease, at the Berlin Medical Society, "the general consensus of medical opinion seemed to be that the number of cases in which asthma was benefited by cauterizing the nasal mucous membrane on the turbinated bones was extremely small."[1]

In summing up this subject, I will quote at present, with some modifications to render it more appropriate to the actual discussion, from a paper written by myself and read in 1886 before this Academy of Medicine. The title of this paper is "Respiratory Neuroses of Nasal Origin."[2] In it I write: "There are, without doubt, a great number and variety of affections, mainly neuroses, under the direct influence of morbid intra nasal conditions; still, at the present time we should be careful not to exaggerate their importance, and, when and wherever we we find a neurosis of the respiratory organs, immediately reach the conclusion that the nose occasions it." There is much truth in the observations of the past few years in regard to the predominating influence of a hyper-sensitive nose, but there is also a tendency to exaggeration in this regard, and we should be careful to exclude other efficient causes of asthma before admitting its nasal origin and instituting severe or prolonged treatment of this organ with a view to cure the possible secondary affection. The nose is naturally a sensitive organ, and many times I have produced epiphora, cough, spasmodic closure of the glottis, moderate in amount, and slight dyspnœa, by the mere passage of instruments or simple nasal examinations, when the result of my further investigation was to show that no nasal trouble of importance existed. This is no

[1] Annual of the Universal Medical Sciences, 1888.
[2] New York MEDICAL RECORD, p. 119, 1886.

new observation, and I am conscious that all of you are familiar with it. In reading the histories of clinical cases we shall be disposed to take a one-sided view, unless we secure the sobering influence which comes from extensive reading and larger experience. The only way, I believe, in which we can avoid error at present in this seductive question, is to search carefully for other cause or causes of asthma; and when none are discovered, then, and then only, we should admit the nasal origin of the neurosis, and institute treatment in accordance with this conviction. I agree entirely with Loblinski, who says: "If there is really a nasal affection, it should be treated according to its character, and not on any far-fetched theory of its etiological importance." [1]

This being my opinion, I must reluctantly separate myself from any such radical position as that upheld by my eminent colleague, Dr. F. H. Bosworth, of New York, who writes that he has seen no case in which intra-nasal disease was not found as a predisposing cause of asthma. And, again, to quote him textually, he has "never known a case of asthma to occur in other than an obstructed lesion of the nose or upper air-passages." [2]

I fear I have left myself but a very short time to allude briefly to other matters of much interest. Ocular symptoms and diseases not infrequently originate from hypersensitiveness of certain intra-nasal areas. These may be photophobia, asthenopia, conjunctivitis, epiphora, contracture of the eyelids, etc. All these I have met with. On two occasions I cured my patients by intra-nasal treatment when that directed to the eye had wholly failed.

The recurring nocturnal cough of children when no pulmonary complications exist, is due frequently to congestion of the posterior portion of the lower turbinated bodies, which produces contact and pressure on the septum at this level. In view of the unique vascular and free nervous supply of this region, the anatomical explanation of this fact is sufficiently obvious. Judicious topical treatment of the nose alone relieves this troublesome symptom. Cough is produced by peripheral irritation engendered by acute or chronic rhinitis.

It is also frequently dependent on nasal polypi, enchondroma, exostoses, and nasal deflections. In the naso-pharynx it may arise from naso-pharyngeal catarrh, or from adenoid tissue at the vault of the pharynx. Hypertrophy of this structure gives rise to congestion of the lower naso-pharynx, and thus increases the sensory excitability.

Palpitation of the heart may become, it is stated, a prominent symptom of the hypertrophy. Chorea, especially of the facial muscles, is not infrequently present. Headache is often complained of, and spasm of the glottis may occur and become a very troublesome symptom. Tornwaldt has found in some instances that the bursa situated in the naso-pharyngeal region becomes diseased and causes, as he believes, hyperæmia and hypertrophy of the nasal mucous membrane. He also reports cases of asthma which were apparently dependent upon cysts in the pharyngeal vault, and which were cured by incision and treatment of these cysts.

These facts are much at variance with Bosworth's explanations as previously reported. In fact, Bosworth confesses his "entire inability to reconcile this statement either with his own clinical observations, or with his knowledge of the physiological and pathological processes of the upper air-tract."

It is interesting to remark that Hack and Tornwaldt both claim that they have in frequent instances cured obstinate cephalalgia by treatment of the naso-pharyngeal disease. Hack advises, indeed, that in all instances of severe headache a direct inspection shall be made of the upper air-tract, in order to discover any possible source of disease in this region. Of course, if it be detected (he says), it should be judiciously treated, and such treatment will be followed by cure of the head symptoms.

[1] Medical Record, May 27, 1887.

[2] American Journal of the Medical Sciences, September, 1888, p. 256.

It is pardonable, I trust, to remark in this place, that one could but sympathize with the poor patient who, under these circumstances, had also a special ocular disease; and, perhaps, also a passing attack of eczema, with evidences of general neurasthenia.

The outcome of such a situation would be four specialists and one general practitioner to help restore the unlucky mortal to a better state of health.

To resume the tenor of my discourse: In common with many physicians, I believe that inflammation of the larynx, trachea, and bronchi is often due to the extension of a chronic inflammatory affection from the naso-pharyngeal space, or to the fact that the secretions make their way down the pharynx and enter the larynx from above. This opinion is directly opposed to that of Dr. Bosworth, who claims, on page 525 of his work on "Diseases of the Nose and Throat," that he "does not suppose that the secretion from the nasal passages or the pharynx ever makes its way into the laryngeal cavity, under any circumstances."

At page 550, Bosworth, in writing of hypertrophy of the pharyngeal tonsil, forgets his previously expressed views for the moment, and unfortunately commits himself to the following statement: "Cough is present in certain cases, especially if there is much secretion which has made its way down the pharynx into the larynx, exciting a laryngitis." I should be glad to know which opinion Dr. Bosworth really adheres to, and if to the one first expressed, how he explains the development of the secondary laryngitis, unless it be from peripheral irritation in the nasal passages.

While I fully recognize that subacute or chronic laryngitis is frequently a secondary condition, and that the nasal passages are the first to become diseased, yet I claim that there are numerous instances in which the laryngitis is unquestionably the primary affection, and should be thus treated.

Follicular pharyngitis often occasions cough. This disease accompanies, or is secondary to, chronic nasal catarrh. The enlarged follicles become painful at times and unduly susceptible to irritation. Frequently the current of inspired air over these inflamed structures produces a short, dry cough, or a constant inclination to "hem." This disease is, also, not infrequently accompanied by marked dysphonia and weakness of the voice, which is apparently due to secondary involvement of the nerve-trunks whose course lies along the pharyngeal walls. The nature of the nervous affection in these, may be either a neuritis or atrophy through pressure from surrounding infiltration of the soft parts.

Enlarged tonsils are occasionally attended with paroxysmal and distressing cough or sudden attacks of dyspnœa, which closely resemble the suffocative attacks of laryngismus stridulus. Sometimes the attacks of dyspnœa are so intense that a sudden fatal termination is feared. They may occur at meals or at night during sleep. According to some authors, the sudden attacks of dyspnœa which afflict children are evidence rather of some rachitic disease of the bones of the skull (craniotabes) than of enlarged tonsils. Irritation of the large lingual papillæ or lymphoid tissue situated at the base of the tongue, when present in excess, occasions obstinate dry cough, dysphonia, and a sensation of stricture around the neck. The latter condition interferes somewhat at times with the powers of deglutition by pressure on the epiglottis, or simply owing to peripheral irritation. These different conditions can be relieved or cured by suitable treatment, sometimes purely medical, sometimes with surgical aid especially directed to the parts involved.

In terminating this brief summary of the subject which has been given me, I would like to add that, had time permitted to read it, it might have been made much fuller and more elaborate. As it is, I trust I have written sufficiently to indicate the points upon which discussion is desirable.

In this place I would remark, by all means let each one

of us look for peripheral irritation in the nose and throat when it seems proper so to do, as a source of disease elsewhere, and when discovered let us treat it rationally, judiciously, and effectively; but not allow ourselves for one moment to believe that the nose or throat, any more than any other organ of the body, is always diseased and should always be treated, either medically or surgically. Keep the general economy in good working order, with some special attention to each organ in a suitable degree and when it is really required, and, take my word for it, there will be much less to do for the rhinologists and for other exclusive specialists, and the majority of people will enjoy more peace of mind and health of body.

To quote from a late editorial of the London *Lancet*[1] and apply it to the subject of debate, I may well add that the study of throat disease "has proceeded along very narrow lines, and pathological theories have been formulated upon insufficient and often erroneous data and made the basis of universal treatment." Some of these views have already "been proved to be wrong, while others are, on the surface, of such an improbable character that they should be received only on the production of irrefutable proof of their correctness."

Would that I could bring to bear on this subject Dr. Goodell's brilliancy of interpretation, and conclude my paper with watchwords analogous to those he has furnished the gynecologists with as broad helps to diagnosis. We may, however, paraphrase one of them with advantage, which is this:

Always bear in mind that men, women, and children have some organs outside of the nasal cavities.

In conclusion, it is well to bear in mind that evidence is forthcoming that the abuse of intra-nasal treatment may carry with it unpleasant consequences. In corroboration of this, I quote from Dr. Rethi,[2] of Vienna, who enters a protest against the indiscriminate use of the cautery and snare in the treatment of intra-nasal disease. Though neuroses arising from disease of the turbinated bodies may often be cured by operation, he has noticed that in some cases they are increased, and that reflex conditions may even be originated by the cicatricial tissue which forms after operations."

INTRALIGAMENTOUS OVARIAN CYSTOMATA.

By ALEXANDER J. C. SKENE, M.D.,

PROFESSOR OF GYNECOLOGY IN LONG ISLAND COLLEGE HOSPITAL, BROOKLYN, N. Y.

The difference between intraligamentous and the ordinary forms of ovarian cystomata is simply in the position they occupy in relation to the ligaments. The location may be called an unnatural one because it differs from that which ovarian cystomata usually occupy.

The intraligamentous ovarian cystomata are, comparatively, quite rare. This suggests that the causes operative in determining this unusual location of these cystomata are exceptional. The literature on this subject is extremely limited. Two theories have been advanced to explain the topographical anatomy of intraligamentous cystomata. The one assumes that, owing to some error of development, the ovary, during embryonic life, finds its way into the folds of the broad ligament and there remains. In that case, if a cystoma of that ovary occurs it is bound to split up the ligament and convert it into a capsule for itself.

The second theory is that during the growth of the cystoma it burrows, so to speak, into the folds of the ligament, and once having insinuated itself there pushes the folds apart, and these folds grow with the cystoma and form a ligamentous capsule for it. In order that this may come about, the ovary must be closely attached to the ligament, in place of being held by a special fold of peritoneum, which leaves it, to some extent, free from the ligament proper. Or the ovary may be bound down to the ligament by an inflammatory adhesion. Where a cyst develops deep in the ovary and meets resistance on the free peritoneal surface, it pushes its way in between the folds of the ligament. There is good evidence in favor of this theory in the fact that these cystomata come from the paroöphoron, which is the portion of the ovary which is nearest to the uterine ligament. Furthermore, I have in one of my own cases found the ovary from which the cystomata came embedded in the posterior fold of the ligament. It would be more correct, perhaps, to say that the ovary was stretched out upon the posterior fold of the ligament. It was so changed in form that I should have overlooked it had it not been that there were several small cysts in it surrounded by what appeared to be ovarian stroma.

In another case I found, while enucleating the cyst, that it was very firmly adherent at a point in the posterior fold of the ligament where the ovary should be found. The vessels were larger at that point than anywhere else, which led me to think that the ovary was there; but the parts were so changed by inflammatory products that I could not positively detect any ovarian tissue. This, I think, is sufficient to settle this point in the pathology and causation of some of these cystomata, and presumably the larger portion, if not all, of such. Still, it may be admitted that malposition of the ovary, because of a lesion of development, may obtain in some cases.

These cystomata may be single or multiple. I think, however, they are more often single. All of my own cases, eight in number, have been monocysts. Another interesting feature is that they are generally papillary or proliferous cysts. This, according to some authorities, notably Bland Sutton, of London, is due to the fact that they are developed from the deeper structures of the ovary, the paroöphoron, as already noted.

The position of these cystomata and their relations to the pelvic organs have a very important bearing upon the question of treatment, as will be seen further on.

In my own practice I have found them occupying widely differing positions, in relation to the ligaments and pelvic organs. In some, the tumor was situated in one ligament, displacing the uterus to the opposite side of the pelvis, and, in a lesser degree, the bladder also. In others the tumor occupied a position in both ligaments and between the uterus and bladder. When thus located the tumor, uterus, bladder, and ligaments have been found high up out of the pelvis, so that the most dependent portion of the tumor could not be easily reached through the vagina. Again, I have found the tumor behind both the uterus and bladder, and yet between the folds of both ligaments. In all of these the pelvic organs were carried up into the abdominal cavity, while the tumor descended deep into the pelvis. It appears that there is a rule which determines the location of those tumors which occupy both ligaments, in regard to their relations to the pelvic and abdominal cavities. This rule may be formulated as follows: When the tumor is between the uterus and bladder all three rise up into the abdomen, whereas if both of these organs are in front of the tumor it dips well down into the pelvis. The reason is that in the one case the vagina arrests the process of burrowing downward, while in the other there is no resistance to the descent of the cystoma.

In all cases the broad ligaments become greatly enlarged and thickened, usually covering the whole cyst, although they are thinned out at the upper portion. When the cyst does not descend into the pelvis and has attained considerable size, the upper portion of the cyst may present a wall of medium thickness; in fact, the ligaments diminish in thickness and vascularity until there is but little left but the peritoneum; and the upper part of the cyst then appears more like an ordinary intraperitoneal ovarian cystoma.

These facts are of the utmost importance in regard to treatment, and hence the reason for this brief account of the various ways in which they may be situated.

[1] February 22, 1890, pp. 412 and 413.
[2] Vide Medical News, March 8, 1890, p. 258.

The diagnosis of such cases is of interest chiefly because of the difficulties encountered in operating and the urgent necessity of clearly comprehending the exact conditions present, in order to manage them to the best advantage. I have found it impossible to make a complete and comprehensive diagnosis in all cases. It is generally possible to make out that there was a cystoma in the broad ligament, but with no definite certainty as to its position and topographical anatomy. Judging from the literature on this subject, it appears that others have suffered from a like uncertainty in some cases. When a cystic tumor in the abdomen which is firmly fixed below, with no history of inflammation during the earlier stages of the growth of the tumor, and the uterus is drawn up out of the pelvis and lies behind or in front of the cystoma, I suspect that it is intraligamentous. If the uterus is displaced laterally in a marked degree by the cystoma that is present, or if the cyst descends deep down into the pelvis while the uterus is high up and in front of the cyst, the facts point to the same conclusion. When a portion of the tumor found in the pelvis is cystic, this is a great aid; but, as a rule, these tumors, as already stated, are proliferous, and there is so much solid material in the most dependent part that fluctuation is not found, and the tumor appears to be solid to the touch and may be mistaken for a fibroma or fibrocyst of the uterus. One case was seen by two well-known ovariotomists, and both suspected fibroma of the uterus as well as ovarian cystoma. My first impressions were the same, but upon opening the abdomen I found the uterus normal, but displaced upward by an intraligamentous ovarian cystoma. Cases may be divided into two classes, those in which a complete diagnosis can be made, and the other in which the diagnosis is incomplete. In the one the nature and composition of the tumor, its relations to the abdominal and pelvic organs, and the extent and location of its attachments can be clearly determined, and the other, which is incomplete but sufficient to warrant either operative treatment or a full assurance that the case is not amenable to surgical treatment. The first or complete diagnosis can be made from the usual physical signs and the history. The incomplete diagnosis may be made complete by surgical means, such as aspirating or by laparotomy. It is of the utmost importance to differentiate between these two classes of cases. When only a partial diagnosis is possible, leaving doubts as to a possible malignant element existing in the case, the question of the propriety of ovariotomy may be determined by an examination of the intraperitoneal fluid, which is often present. If this proves negative, the operation is advisable; while if the cells characteristic of malignant disease are found, the case should be left alone. Keeping still to the question of diagnosis, I may say that in cases of intraligamentous cystomata one can usually make sure that an operation is called for and is justifiable, but the diagnosis must often rest as incomplete until the abdomen is opened. At the same time it is not an easy task to complete the diagnosis after laparotomy. A few words on this subject may be admissible, in view of the importance of the matter. We hear much of making an exploratory operation for diagnostic purposes, but I am satisfied that skill and experience are very necessary to do this. To recognize just what is present, and to determine what to do in these cases when the tumor is exposed, is no easy task; and still, upon a rapid inspection and palpation and prompt decision regarding the exact conditions, and how to manage them, depends the success of the surgeon in complicated cases. I may not have seen or carefully thought of all the conditions which simulate, and hence may be mistaken for, intraligamentous cystomata, but such observations as I have made cover the most important part of the ground.

When the tumor is exposed by laparotomy its appearance resembles most closely a uterine fibroma, and owing to the thickness of its walls it feels to the single touch, especially if the cyst is very tense, as usually is the case, like a fibroma; but by resting one finger on the tumor and percussing the abdominal wall at a distant point, fluctuation can be unmistakably made out. This settles that point at once, but leaves still the possibility of a uterine fibrocyst, and although this is not important as bearing upon the main question of removal of the tumor, it affects the method of procedure and should be correctly decided at once. This can be done by tapping, which shows the character of the fluid, which is all sufficient, with few exceptions. If pus is found it may be impossible to say whether the cyst is uterine or ovarian. The tapping, however, gives more room for the introduction of the hand, which enables the operator to make out the attachments and the relation of the tumor to the pelvic organs, and thereby complete the differentiation.

The pregnant uterus also looks, in color and vascularity, like this form of tumor, and may lead to doubt. At least I think that when this mistake has been made, an intraligamentous tumor must have been suspected, because it is the only ovarian cystoma that appears at all like the uterus. This can be made clear by observing contractions of the uterus, which can be easily excited, and by passing the hand into the abdomen the ovaries can be found, and the cervix uteri and normal ligaments will show that there is pregnancy.

These tumors require special treatment, owing to the fact that they are not pedunculated like the ordinary cystomata, but are encapsulated and differ in their relations to the pelvic organs.

The several methods adopted in operating are as follows: Enucleation ranks first, because it is adapted to more cases perhaps than any other. This well-known method, devised and introduced by Dr. Miner, of Buffalo, has been practised by many ovariotomists. It was employed in the treatment of ordinary pedunculated cystoma when first brought out, and is now seldom practised except in parovarian cysts. In fact, I do not think that Dr. Miner ever employed his method in the treatment of the class of cases now under consideration, but if he did, he omitted a description of some of the details which are necessary. Enucleation is adapted to all cases in which the cystoma descends into the pelvis, completely separating one or both ligaments. In all such cases it should be tried, and it will succeed well unless there has been inflammatory action which has firmly united the cyst-wall and folds of the ligaments, or the cyst-wall is thin and friable.

In such conditions the enucleation may prove to be impossible, and other means of treatment, to be hereafter noted, must be adopted. In the first place, it is important to tap the cyst high up in order to avoid wounding the thickest portion of the broad ligament. To do this it is sometimes necessary to extend the incision in the wall of the abdomen higher than usual. The cyst being emptied and drawn well out of the wound, the separation of the ligament and cyst-wall should be begun at that point high up where the ligament is so thinned out as to be hardly noticeable. When the dissection is begun all around, the capsule can be lifted up and the dissection continued with the knife-handle, and finally the deeper portions can be separated with the finger. The traction should be made upon the cyst-wall, as the capsule or ligaments are easily lacerated. During enucleation, if any large vessel, artery, or vein is injured, it should be ligated or controlled with forceps at once. The management of the ligaments, after the cystoma is removed, is first directed to the control of hemorrhage. In some cases a general oozing is all that there is. Occasionally a wounded vessel here and there needs ligating. When the cyst extends deep down into the pelvis there is often very troublesome bleeding from veins. These should be ligated, if possible; but if that cannot be done, pressure with a hot sponge should be tried, and, if that fail, styptics may be used. The ligamentous capsule now presents a pouch, the inner surface of which is raw, and from which there will be some bleeding and much serous oozing. This should be treated as follows: The

upper portion of the opposing sides should be folded in so as to bring the peritoneal surfaces together, and these should be fixed by a continuous catgut suture. The suturing should begin on both sides, and be from the sides toward the centre, and close the parts, except at a point beneath the abdominal wound, where an open space should be left for the drainage-tube. If the ligaments thus brought together by sutures can be brought up to the lower angle of the abdominal wound, they should be fixed to the abdominal wall by silk sutures passed through the ligaments on each side of the opening for the drainage-tube, and then through the wall of the abdomen. When the ligaments cannot be brought up to the wall of the abdomen a drainage-tube without side openings should be carried down to the bottom of the cavity.

While this mode of treatment is perfectly satisfactory in suitable cases, there are difficulties attending the operation in exceptional cases, and hence certain dangers. The cyst-wall may be easily torn, and hence the danger of leaving portions of it. When this happens it is necessary to destroy the secreting surface. This may possibly be done by applying pure carbolic acid. The most diffi cult part of the operation, in some cases, is to stop the bleeding. This has been referred to; but I may say further, that the oozing at the time of operating, and the liability to suppuration which may occur afterward, render the convalescence rather tedious in many cases.

The next procedure is to remove the cystoma, and its capsule also, by ligating the ligament below the tumor. This method is adapted to those cases in which the cyst is situated in one broad ligament and does not dip down very far into the pelvis. Such cases are described in books as having a very broad pedicle, but the most that can be correctly said of them is that they are partially pedunculated. In this condition the ligament can be ligated with the repeated continuous ligature. This is applied in the following manner: One end of the ligature is passed through the ligament and a portion of it tied, then one end of the ligature is passed through the portion already ligated, then carried forward, and brought back through the ligament in such a way as to secure another portion, and the two ends again tied, and so on until the whole is secured. The cyst and its capsule are then cut off. This leaves no cavity, arrests all possible hemorrhage, and in this respect is all that can be desired. But there are difficulties and dangers that may arise, even in cases where it is applicable. There is danger of wounding the ureter or including it in the ligature. A knowledge of the location of the ureter and its anatomical relations are not always sufficient to guard against this accident, because the ureter may be displaced. By drawing the cyst and ligament out of the abdominal wound it may be possible to see that the ureter is not in the way; but this cannot always be done, and then one has to depend upon the touch to localize the ureter and avoid it. This is possible, owing to the fact that the ureter feels like a cord crossing the ligament, but in case the tissues are thickened by inflammatory products it is difficult indeed to find the ureter.

There is still another way of managing these cases, and that is a combination of the two methods already described. It is well adapted to cases that can be enucleated easily, and has the advantage of surely avoiding the ureter. The cyst is first enucleated, and the capsule, or so-called pedicle, is tied and cut off. The advantages are that the capsule is easier to be handled after the cyst is removed, and there is no danger of including any portion of the cyst in the ligature, an accident that may occur in operating by the second method alone. There is one fortunate feature in this method of treatment, viz., in case enucleation cannot be effected ligation alone can be resorted to. It is well, then, to try enucleation, even if it has to be abandoned.

There still remain for consideration cases that cannot be removed by any of the methods known at the present time, and there are such. A cystoma that descends into the pelvis and has become firmly adherent to the ligaments by inflammatory products cannot be enucleated, neither can the capsule be ligated. At least enucleation cannot be done with any degree of safety. That complete removal of such tumors has been tried is no doubt true, but the result has been to open into the rectum, and cause uncontrollable bleeding or peritonitis, either of which must prove fatal. These complications are always present in suppurating intraligamentous cystomata, and hence when pus is found on tapping it may be inferred that enucleation is impossible. I have found, however, that a non-suppurative cellulitis has so firmly united the cyst-wall to the ligamentous capsule that they could not be separated. The treatment of such cases is by drainage. I am well aware that the more skilful the operator the more surely will he overcome difficultics, and more seldom will he have incomplete operations; but when the conditions which have been named are present, I am confident that it is wiser and better to empty the cystoma and unite the cyst-wall to the abdominal wall, and then drain by means of the ordinary tube. The cyst fluid is usually septic (this is always so in suppurating cysts), and it is very difficult indeed to save the peritoneum and abdominal wounds from contamination. After emptying the cyst and opening it, it should be thoroughly cleaned out with sponges or absorbent cotton, and papillary tissue, if present, may be scraped off. This should be done with the cyst drawn well out of the wound. If the cystoma is large, an effort should be made to separate the cyst-wall capsule as far down as possible. If that can be done, the detached portion of the sac is then cut off, taking care to have it so that the central portion will come up to the abdominal wall without dragging. Bleeding vessels in the cyst-wall are ligated or twisted. The detached portions of the capsule are folded into the cyst and united with a continuous suture, beginning on each side and continuing toward the centre, but leaving space enough between their meeting to admit the drainage-tube. In doing this, great care has to be taken to keep the hands and instruments which have touched the inside of the cyst from coming in contact with the peritoneum or abdominal wound. Again, in fastening the partially closed cyst to the abdominal wall, it is necessary to pass the needle from the abdominal wall into the cyst, and not use that needle again unless it is thoroughly cleansed. If, on the contrary, the sutures are passed from the inside of the cyst outward, septic material will surely be carried into the tissues of the abdominal wall, and trouble will follow. One suture on each side of the opening in the cyst for the drainage-tube will suffice to unite the wall of the cyst and the abdominal wall at these points, and one suture above, and one below, carried through the sides of the abdominal wall, and into the cyst-wall, but not through, will complete the coaptation. If this much is accomplished without contaminating the normal tissues there is very little danger of septic peritonitis occurring, or septic inflammation of the abdominal walls. The drainage is so perfect that though suppuration in the remaining portion of the cyst may go on, there is not much danger from it if it does not extend outside the sac. The drainage must be long continued, and the convalescence is very slow, comparatively. In case the secreting surface of the cyst has been thoroughly destroyed by suppuration the recovery is usually not long delayed. Contraction and closure of the cavity comes in a month or thereabout. If, on the other hand, the secreting surface is left, the discharge may go on for months; but the patient, meantime, may completely regain her health and be able to attend to her duties comfortably. When a small pocket and sinus remain, it facilitates recovery to inject iodine or carbolic acid. I may be prejudiced in favor of this mode of treating such cases from the fact that I have had two intraligamentous cystomata and four adherent ordinary ovarian cystomata which were treated by drainage, and all recovered.

THE ULTIMATE RESULTS OF LAPAROTOMY FOR THE REMOVAL OF DISEASED APPENDAGES.[1]

By H. C. COE, M.D.,

NEW YORK.

When the president made a personal request last fall that I would introduce a discussion on this theme I declined, saying that, in the first place, I was not a laparotomist, and that, in the second, it would be more fitting for an older and more experienced observer, such as are the gentlemen who will follow me, to assume this duty. When the request came through another channel I was induced to accept the responsibility, with the distinct understanding that the discussion would be rigidly confined to a statement of anatomical and clinical *facts*, and not to a rehearsal of individual triumphs in abdominal surgery. With these triumphs we are already sufficiently familiar. The brilliant results of our honored Fellows, Dr. Wylie, Dr. Mundé, Dr. Tuttle, and many others of whose success we are proud, need no additional words of approval; their statistics speak for themselves. The indications and contra-indications to laparotomy for removal of the adnexa we have discussed time and again. The changes on the subject of conservatism have been rung so often that professional audiences are beginning to weary of them. I dismiss this phase of the question entirely, and invite your discussion of the subject as announced, which is *not* the limitations of laparotomy for ovarian and tubal disease, *not* the number of difficult and successful operations which you have performed, but the condition of your patients a year, two years, or five years after recovery from the operation. I am aware that operators of the largest experience are often unable to trace the majority of their charity patients after they have been discharged from the hospital. It is for this reason that I have ventured to introduce this subject, in spite of my limited experience as a laparotomist, because it seems to me that the dispensary physician is in a better position to judge of the after-effects of laparotomy than is the distinguished surgeon whose interest in the patient often ceases as soon as he has written "R," after her name in his table of statistics. As I take it, the object of the present discussion is to decide the question whether the word "recovered" as applied to these cases is synonymous with "cured." By the "ultimate results" of laparotomy, I understand that reference is made to the condition of the patient after the lapse of at least a year after the operation, when it is fair to assume that the usual symptoms referable to the sudden and artificial establishment of the menopause (flushing, metrostaxis, various nervous phenomena, etc.) ought to have disappeared, or, at least, to have become endurable. This excludes certain secondary, or remote local complications, such as acute pelvic abscess, intestinal and vesico-vaginal fistula, fistulous drainage-tube tracts, mural abscess, ventral hernia, etc., which might be ascribed either to accidental causes or to some fault of the operator. We shall assume that the operation was performed strictly *secundum artem*, according to the most improved modern methods. Moreover, it will be impossible to discuss at length the results of removal of the adnexa on one side only, in spite of the interest attaching to this subject, as it would divert our attention from the main issue. Assuming that we have all had the most gratifying results follow laparotomy, as regards not only the actual preservation of the patient's life, but also her restoration from invalidism to perfect health, I shall confine myself entirely to a rehearsal of the permanent ill-effects which may follow even the simplest and least complicated operation, leaving it to you to explain why they occur, and how they may be avoided.

For convenience we may consider these under two general heads, viz.: 1, Psychical results; 2, physical results. Under the first should be included not alone the transient "psychoses," to which attention has recently been directed as sequelæ of gynecological operations, minor as well as major, but actual insanity. I do not feel competent to express an opinion upon this subject, as the facts at my command are too few to warrant it. In a recent conversation with a prominent alienist, he stated his belief that most of the cases of insanity reported as directly due to removal of the ovaries were open to suspicion, because a careful study of the patient's history would generally show that her mind was already so affected before the operation that she would probably have become insane even if it had not been performed. On the other hand, a gentleman connected with a large asylum stated, in a paper read by him not long since, that at least ten per cent. of the women whose tubes and ovaries were extirpated became insane in consequence. I am sure that this must be an exaggeration, at least I have never noted any such proportion, nor does any other author make such a sweeping statement. Careful observers do hold that there is a direct relation between the operation and the subsequent mental aberration which sometimes occurs. We ought under this head to consider the question of the "unsexing" of women by the operation, one which figured in a recent medico-legal case. We should settle this matter definitely so far as we are concerned. The physical results of laparotomy for removal of the adnexa may be general or local. Under the former are included the various neuroses which persist for years after the operation, circulatory abnormalities, such as true cerebral hyperæmia (to which I have called attention in a former paper), and various visceral disturbances, especially intestinal troubles due to adhesions. The latter I have considered elsewhere. All who have had occasion to perform laparotomy for the second time on the same patient, will agree with Martin as to the frequency of localized peritonitis in apparently aseptic cases. Peritonitis means adhesions, the influence of which on distant viscera I enumerated in a paper on "Visceral Lesions due to Localized Peritonitis." I can only touch on these points and leave their further consideration to you. I have been especially interested in the local, or intra-pelvic complications of laparatomy, yet this division of the subject is too broad to be covered by me in the brief time allotted, and as you are already tolerably familiar with my views I can merely outline my position, which is as follows: The persistent pelvic pain, congestion of the uterus (with or without a pseudo-menstruation), vesical and intestinal disturbances, which in a certain proportion of the cases are noted for years after removal of the tubes and ovaries, are directly due to intra-pelvic indurations or adhesions, which may have existed before the operation, or may be the result of localized peritonitis following it. If adhesions existed before the operation and are separated at the time, they are very apt to reform, especially the intestinal. Small indurations around the stumps, or in the broad ligaments, are sufficient in themselves to cause constant severe pains, both local and reflex, and to induce a more or less permanent pelvic congestion. Even when ventro-fixation of the uterus is practised, we cannot be sure that the organ will undergo post-climacteric atrophy. Intestinal adhesions are of common occurrence, indeed their absence is a matter of surprise when we consider the fact that the coils of gut must always lie in direct contact either with the stumps alone or (in complicated cases) with large, raw surfaces in Douglas' pouch, and on the posterior aspect of the uterus and broad ligaments. Such adhesions, even when slight, may give rise to severe and irremediable colicky pains; when more extensive, the patient is in constant danger of intestinal obstruction. When for any reason the adhesions around the uterus and adnexa are separated without removal of the latter, they unquestionably reform, either at the old, or at new sites. When diseased adnexa —a pyosalpinx, abscess, or adherent cyst—is emptied and fastened in an unnatural position, as in the abdominal

[1] Introducing a discussion of this subject before the N. Y. Academy of Medicine, March 6, 1890.

wound, even if the intestines do not become adherent to it, undue traction is made upon the pelvic organs (and especially upon the neck of the bladder), thus giving rise to permanent distressing symptoms. I can only add to this brief review of the possible local complications following laparotomy, that as yet we possess no sure means of avoiding them. Rigid antisepsis, absolute hæmostasis, cauterization of the stumps, and even of all new surfaces, the routine use of intra-peritoneal irrigation, and the removal of the water by siphoning alone, with the absolute interdiction of sponging, careful arrangement of the intestines and peritoneum before closing the cavity, early removal of the drainage-tube—all these precautions have been adopted, and yet intra-pelvic adhesions have formed, and that too in perfectly uncomplicated cases, in which the pelvis was absolutely free from adhesions when explored at the time of the operation. It seems to be practically impossible to predict that localized peritonitis may not develop in any given case, however favorable it may be. I dislike to dismiss this subject so abruptly, but my duty is simply to outline it, not to fill in the details. I trust that the discussion will be confined within the prescribed limits, as the introduction of outside issues will only complicate what is already a difficult question.

The following are brief notes of a few of my own cases, in which I have had the patients under observation since the operation. I might cite many more in which laparotomy was performed by other surgeons, and the patients subsequently came under my care on account of resulting troubles, but I do not think that it would be proper for me to do so.

Case I.—Mrs. W——. Laparotomy, October, 1885. Double intraligamentous cyst with pyosalpinx. Operation complicated by general intestinal adhesions. Cyst on right side enucleated and removed with the tube. Left tube removed and cyst drained and stitched in the wound. Good recovery. Patient still under treatment for persistent pain and dysmenorrhœa. Until recently was obliged to pass her water every hour or two. Severe vesical tenesmus. The uterus is drawn upward and is adherent to the left side of the pelvis, constant traction being thus exerted upon the neck of the bladder. I have treated her at intervals for over four years with only temporary benefit. Her discomfort has been such that she considered the advisability of submitting to a second laparotomy.

Case II.—Mrs. D——. Typical history of gonorrhœal salpingitis. Uterus retroflexed and firmly adherent, with double pyosalpinx. Constant pain and severe dysmenorrhœa. Was under regular treatment for over one year without benefit. Laparotomy, September, 1887. Adhesions broken up, appendages removed, ventro-fixation of uterus. Convalescence rapid. The patient was relieved for several months, after which the pain returned. I saw her about three months ago. She had not menstruated since the operation, but had the same pain in the back and abdomen as before, with marked vesical irritation. The uterus was small and anteverted, but there was considerable tenderness around the stumps. The patient was greatly depressed and in poor general health.

Case III.—Miss L——. The tubes and ovaries were removed in 1885, for the relief of dysmenorrhœa. Convalescence normal. She attended the Polyclinic regularly after leaving the hospital and subsequently remained under my constant observation in various institutions until her death in 1889. Though menstruation ceased, she was never free from pain after the operation, neither was I able to afford her any relief by the ordinary local treatment, including the use of galvanism. Persistent pain had been substituted for the monthly paroxysms. It was always localized in the right side, where an induration the size of a walnut could distinctly be felt. Constant and agonizing vesical tenesmus. Repeated examinations of urine with a negative result. One of her most obstinate and distressing symptoms was more or less constant cerebral hyperæmia—not the ordinary climacteric "flushing"—which grew steadily worse. She insisted on a second operation, which was performed by the late Dr. Hunter, and terminated fatally. The induration in question was found, but could not be removed. At the autopsy an indurated mass was discovered at the site of the right stump which pressed the ureter, causing pyonephrosis of the corresponding kidney. The uterus was latero-flexed and firmly adherent. It would have been impossible to cure the patient without performing nephrectomy, and the condition of the kidney was, of course, unsuspected.

Case IV.—Mrs. C——. Double pyosalpinx and chronic oöphoritis with firm adhesions. Laparotomy October, 1888. Rapid convalescence. Both ovaries removed. The patient still menstruates regularly and with more pain than she had before the operation. There is a large mass at the site of one of the stumps. Her condition is worse than before.

Case V.—Mrs. T——. Under constant treatment for nearly a year, and grew worse, rather than better. Both ovaries adherent in Douglas' pouch, enlarged and extremely tender. Constant pelvic pains, severe dysmenorrhœa, and menorrhagia. Laparotomy, December, 1889. Diseased tubes and ovaries removed. Patient made such a rapid recovery that she was up at the end of three weeks. She has precisely the same pains as before, and has a constant sanguineous discharge, but does not menstruate. The uterus is in normal position, but is large and sensitive to the touch. Marked tenderness around both stumps.

Case VI.—Miss O——. Was an unusually robust young woman. Laparotomy was performed for the relief of pelvic pain and dysmenorrhœa in December, 1888, diseased ovaries and tubes being removed. Convalescence normal. She was discharged apparently well, but came under my care in the clinic six months later, saying that she was worse than ever. Menstruation had ceased since the operation, but she had a constant agonizing pain in the left side, so that she was unable to walk. Constant severe frontal headache. On examination an extremely tender mass was felt at the site of the left stump, exactly similar to that mentioned in Case III. Life was a burden to her, and with her cheerful consent I opened the abdomen a second time about two months ago and found the mass as previously located. It proved to be a knuckle of intestine which was firmly adherent to the left stump. It was separated with considerable difficulty, and at imminent risk of tearing the gut. When freed, the adherent surface presented an ulcerated spot the size of a quarter of a dollar, with hard raised edges. The advisability of resecting the intestine occurred to me, but I finally decided to cauterize the ulcerating surface and return it to the cavity. Thorough irrigation and drainage. Convalescence uninterrupted. Bowels moved spontaneously on the second day. When examined a few days ago all trace of the induration had disappeared, and there was no local tenderness. The bowels are constipated and the patient has severe colicky pains, so that I suspect a fresh adhesion of the gut. The headache is worse than before the second operation.

Case VII.—Mrs. B——. Was operated upon a year and a half ago by a prominent laparotomist of this city. She had constant pain in the left side and dysmenorrhœa. Pyosalpinx and diseased ovary on the left side removed. After the operation the pain was transferred to the right side and was worse than before. Has had several attacks of localized peritonitis. I first examined her three months ago. There was general tenderness around the uterus, which was in normal position. To its right there was a mass the size of a Messina orange, exquisitely tender to the touch. Diagnosis, cystic ovary and pyosalpinx, which was confirmed at the operation a month later. The coils of intestine within the pelvis were generally adherent to one another and to the tumor; intestinal adhesions along the line of the former incision. The adhesions were thoroughly separated and the tube and ovarian cyst were removed, leading to profuse hemorrhage, which was

checked with difficulty. Irrigation and drainage. Rapid convalescence without elevation of temperature. The patient now complains of the same pain on the right side; on examination a tender induration can be felt at the site of the right stump; pressure upon which causes a paroxysm of pain which lasts for an hour.

Case VIII.—Mrs. A——, double pyosalpinx, removed in September, 1889. Convalescence normal until the second week, when there was a transient elevation of temperature, accompanied by severe pain in the right groin. Vaginal examination revealed an induration around the stump, which is still present after the lapse of six months, the patient having constant pain in the right side, which prevents her from attending to her household duties. She had no metrostaxis until three weeks ago, when she reported to me on account of profuse flow. I found the uterus small, in normal position, and quite tender to the touch; the induration to its right was smaller than it was two months before, but was still very sensitive. The patient was greatly depressed because she was no better.

I present the above facts without comment, and could easily double and treble the number of cases. If with my limited experience I have observed so considerable a proportion in which laparotomy is not followed by permanent benefit, at least so far as regards the relief of pain, those operators who number their cases by hundreds could, if they would, add much to our knowledge in this direction. Unfortunately, there is a singular reticence on the part of surgeons with regard to the ultimate results of their operations, provided that these are less successful than they expected.

So far as I am concerned, whenever this subject is introduced I shall never cease to insist upon this truth, which I have repeatedly demonstrated to my own satisfaction in the examining-room, at the operating-table, and in the dead-house—that recovery from laparatomy is *not* synonymous with cure.

MEDICAL CASES OF INTEREST.

By HENRY A. RILEY, Esq.,

NEW YORK.

A recent interesting case in New York, involving the subject of insanity, decided some points of importance. The case was that of a son who petitioned the court to have his father declared a lunatic and unable to manage his property. The father was adjudged by the jury to be insane and to have been so for several years previous.

About a year before this verdict was rendered the father had deeded to his son an island in the Niagara River, containing about one hundred and fifty acres, on condition that the son support and maintain his wife and himself during their lives. It was claimed that the verdict of the jury in the lunacy commission case, to the effect that the father had been insane for several years, made the deed void, and it was further claimed that the son being the petitioner in the lunacy case was estopped from showing that the father was sane at the time of executing the deed. The Court of Appeals examined with some care the interesting questions involved in this incomplete statement of the case, and decided that the son, although the active mover in the lunacy case, was not such a party in interest as to prevent him from showing his father to be sane when he executed the deed. It was also held that the statement by the jury, that the party had been insane for several years, was incidental only, and not absolutely binding in another suit where the title to land was in question. In most lunacy proceedings the vital question is whether the person is at the present time insane.

The Nation recently reviewed Hon. Reuben Davis's "Recollections of Mississippi," and in the article are the following remarkable statements about the regard then felt toward human life, and the requirements of the Code: "In 1832 Mr. Davis passed from medicine to law and began its practice at Athens, with a young wife and but three dollars in his pocket. What a passion there was in the community for litigation is shown by the fact that in four years he had saved twenty thousand dollars. At the Spring Term of the County Court, in 1835, he brought four hundred and eighty suits. Made District Attorney, a frequent source of embarrassment was that in criminal suits the murderer was a personal friend, 'for whom he had respect and friendship,' and whom he thought 'justifiable under the circumstances of the killing.'

"Once when he had witnessed the murder, his embarrassment was so great that he went into court with five hundred dollars in his hand, with which he asked the court to furnish counsel for the prosecution.

"When another friend, shortly after, killed his man, Davis resigned his office, and tendered his services in his defence. He pulled him through.

"'Since that day,' he writes, 'I have defended over two hundred cases tried for murder, and never had the misfortune to have my man hung.' Could any statement be more expressive of the quality of mercy in the administration of justice? It is very clear it was not strained. Davis had never a doubt himself of a man's right to defend his person or his honor at the risk of another's life. With him it was a word and a blow, and if the blow was not first it was nearly simultaneous. He could not have been more than seventeen when he had his first personal encounter. There was a question of precedence of claim upon the attention of one of the ladies at a ball. 'I no sooner withdrew my adversary from the ladies than I challenged him to defend himself, and assaulted him with my pocket-knife. . . . This action I never regretted, holding that a man has a right to defend his honor whenever and by whomsoever assailed. Had I submitted tamely to this insult, my whole future career would have been blighted by it, and I should have lost all claim to the respect and good opinion of my fellow-citizens.'"

Since the time to which Mr. Davis refers there has been a great change in Southern sentiment regarding the necessity of protecting what is thought to be one's "honor" by the shedding of blood, and this change is very largely due to the different conditions of life prevailing since the Civil War. It will be many years, however, before it will be thought honorable in all communities not to avenge an insult by a bullet. So long as family feuds have so slight an occasion and so bloody a termination as in some of the mountain counties of Kentucky and West Virginia, within the past two years, it cannot be said that the rules of modern civilized life have universal sway.

So long as a dispute over a newspaper article leads a correspondent to shoot, in the very precincts of the National Capitol, a former member of Congress, it can hardly be thought that the ante-bellum ideas of "honor" have become obsolete; and so long as the brutal pounding of the prize-ring is regarded as a fine athletic exhibition by the best citizens of a Mississippi county, and the principals are aided in every way to avoid punishment, even the honorable efforts of a governor to secure conviction will not relieve the State from the stigma of brutality.

The New Jersey statute passed in 1886 provides that no person shall sell any oleomargarine, "unless he shall first inform the purchaser that the substance is not natural butter or cheese, but imitation," and shall also at the time of sale "give to the purchaser a card or notice, printed on which shall be the name of the substance sold, and the name and address of the seller or vendor.

In a suit to collect the penalties under this act, which were $100 for the first offence and $200 for a second or subsequent offence, it was claimed that the buyer was informed orally that the article was oleomargarine, though it was admitted that no printed card or notice was handed to the buyer. The failure to give this notice was held to warrant a recovery, the oral notice being insufficient. It was also claimed that it did not appear that the article sold

was deleterious to health, and that no deception whatever was practised on the buyer. This defence the Court held was not a pertinent one, as the statute made no distinction between different kinds of oleomargarine, but stated that the sale of any kind of oleomargarine or imitation butter was not permitted, except as specially authorized.

In general, it may be said that lack of knowledge on the part of the seller that articles sold are adulterated, will not free him from any penalties given in the statute. The seller is bound to know the character of the wares he sells. In a case decided a short time since by the New York Court of Appeals, where damages were claimed from a railroad company for an injury suffered when crossing the track, the Judge charged the jury that "the expenses of recovery as regards the past and the future" could be considered in deciding upon the amount of the verdict. It seemed that the plaintiff had not fully recovered from the injury, and though he did not prove the value of the medical services which would be required, nevertheless, the defendant did not ask for an instruction limiting the verdict to nominal damages. The Court said: "It may now be regarded as settled that the jury, in cases of this character, may take into account the pain and suffering that may reasonably be expected in the future, provided evidence has been given tending to show that the person injured will probably experience further pain as a result of the injury."

Clinical Department.

A CASE OF TREPHINING FOR FRACTURED SKULL—RECOVERY.

By GEORGE L. RICHARDS, M.D.,

EAST GREENWICH, R. I.

The following case is of interest on account of the severity of the injury produced by the throwing of a stone—a practice common among boys when angered—and also because of the excellent result following the operation of trephining.

In Apponaug, R. I., about 9 P.M., August 6, 1889, E. F——, aged sixteen, while engaged in a boyish quarrel with a negro was hit with a stone thrown by the latter. He instantly fell, and when picked up was unconscious. He was at once taken to the office of Dr. J. B. Hanaford, who found evidence of concussion of the brain and fracture of the skull.

Early the next morning there was partial consciousness, but this being all there was of gain, and the condition not improving during the day, I was called in consultation.

At the time I saw him, 4.30 P.M., August 7th, the boy was semi-conscious, unable to speak, and partially paralyzed on the right side. Over the left parietal bone, at about its centre, was a slight cut one-half to three-fourths inch long, one-sixteenth inch deep, which had bled a little. No other external mark was seen. On palpation just above the skin cut a sharp depression was felt. In every other direction this depression gradually diminished. Diagnosis—depressed fracture of the skull with compression of the brain. As he was growing rapidly worse we decided that the only thing to do was to cut down to the bone, and raise the fragments, trephining if necessary. The family consenting, the patient was etherized, and the head shaved and made as antiseptic as possible. I then made a semicircular incision, three inches long, over the centre of the left parietal bone, and to the bone. The skin flap being dissected up revealed a depressed comminuted fracture of the left parietal bone. Going from above downward, from sound bone, there was a sharp depression, the jagged edges of which were two and three-fourths inches long and three-eighths inch deep. From above downward it was one and three-quarters inch before sound bone was again reached. There were three comminutions of the depressed portion, one of them being still further depressed, so that its depth as compared with the normal condition was three-fourths inch. Hemorrhage over seat of fracture was but slight. A slight attempt at elevation was made, without success. The trephine was then used, and from the uninjured bone of the upper border a button half an inch in diameter was removed without injuring the dura mater. With some difficulty, owing to the slanting edges of bone being firmly wedged together, the depressed portions were elevated and restored to about normal position. A few splinters of bone were removed. The wound was then thoroughly cleansed with corrosive sublimate 1 to 2,000, the button of bone replaced, drainage-tube inserted, and wound closed with deep and superficial silk sutures, except at the lower margin, to allow of free drainage. Iodoform and an antiseptic absorbent cotton dressing applied. Toward the close of the operation the patient had a slight rigor and was given brandy, ʒ ij., and morph. sulph., gr. ¼, hypodermically. Pulse, 72 and good; the operation took about one hour.

The subsequent history of this case was all that could have been desired. The dressings, which were renewed at first every other day, and then at longer intervals, were never stained through, and the temperature never rose above normal. On August 9th, two days after the operation, the patient could sit up and was conscious, though swallowing with difficulty. He tried to talk, but could not. August 11th wrote his name. August 14th began to talk a little. August 23d wound had healed everywhere and stitches removed. August 27th drainage-tube removed; the patient was allowed to go out of doors; speech and deglutition all right.

September 12th in court, gait somewhat staggering; was able to give a very intelligible account of events up to the moment of injury, after which everything is a blank.

Dr. Hanaford tells me that in October he removed a spicule of bone which had worked through the skin; a bit of bone probably too much injured to regain its vitality.

The boy is now in good health and apparently as well as ever.

I am of the opinion that had we used absorbent gauze, and not changed the primary dressing for a week or ten days, it would have been as good, perhaps better, surgery, though no case could have done any better than did this one.

FRACTURE OF THE CONDYLE OF THE OCCIPITAL BONE.

By WALTER F. MORGAN, M.D.,

LEAVENWORTH, KAN.

April 21, 1889, I was called to see P. D——, a colored coal-miner, aged about thirty-five years. His wife gave the following history of the case:

About three years and four months since, he was injured in a mine by the falling upon him of a mass of slate, after which for a long time he was unable to turn his head to the right He partially recovered from this accident, and was able to resume the occupation of a coal-miner. Last December, about Christmas, while working in a mine, he was again injured in a manner quite similar to the accident before described, and was never able afterward to move his head in any direction or to work again in the mine. About February 25th symptoms of hemiplegia supervened, and soon he was obliged to take to his bed, from which he never arose.

Status presens.—Patient on back, with head rigidly fixed and turned toward the left, instead of right, as after the first injury. Eyes looked bright and natural, and the mind seems perfectly clear; appetite good. Paralysis of both upper and lower extremities on right side, involving sensory and motor fibres; on the left side the prick of a pin can be felt and the fingers, after massage, can be slightly flexed. There is little complaint of pain, except when clonic spasms occur, which happen at irregular in-

tervals. Patient allows no one to move his head except his wife, and then the whole body must be moved. When carefully questioned the wife thinks she has occasionally heard, in moving patient's head, a noise like the cracking of one's knuckle-joints.

I diagnosed fracture of one or more cervical vertebræ, and gave an unfavorable prognosis, and suggested a consultation, but the suggestion was not acted upon.

Two days afterward (April 23d), at about 5 o'clock A.M., his wife tried to move his head, when, suddenly, there was a yielding of the tissues of the neck, which entirely relieved all rigidity. At 9 A.M. the patient asked for some breakfast, and when his wife brought it, a few minutes later, he was dead. This sudden death was probably caused by an unguarded movement, producing compression of the cord.

Autopsy, twenty-four hours after death, Drs. Samuel Phillips and John J. Edic being present. Upon a vigorous rotation of the head no crepitus was elicited, but when a firm and sudden pressure was made upon the nucha—subject lying prone—crepitus became audible, the right transverse process of the atlas was found destroyed by caries, the articular surface of its lateral mass about half absorbed by the chronic inflammatory process to which the region had evidently been subjected, the right condyle of occipital bone in a condition similar to that of the transverse process of the atlas. A detached piece of bone was found, which had been a part of the condyle, presenting a groove corresponding to one-half of the anterior condyloid foramen. The axis was intact except the odontoid process, which was denuded of cartilage and roughened on one side. The check ligaments seemed to have become disorganized.

The patient had consulted several physicians, and had been treated for rheumatism. No one seemed to have made much effort to arrive at a correct diagnosis, and hence at correct therapeutics. "Wood's Handbook" mentions that rheumatic symptoms are occasionally associated with chronic inflammation of the spinal cord.

Aside from the intrinsic interest of this case, it is reported in the hope that it will be acceptable to the general practitioner, on account of its unique history and the probable rarity of this form of accident.

A SIMPLE METHOD OF CONTROLLING OBSTINATE EPISTAXIS.

By A. W. FRIDENBERG, M.D.,

NEW YORK.

Not very long ago a man walked into my office bleeding profusely from the right nasal cavity. He had had similar attacks on previous occasions, which were always very difficult to manage, and during one of them he had nearly bled to death, despite the efforts of the two physicians in attendance. He had finally to be transported to the hospital, where the hemorrhage was checked with the assistance of Bellocq's cannula. The present attack had lasted three or four hours, had resisted the usual means of treatment, and the patient declared he had lost a pint of blood. During the ten minutes or so that he had been awaiting his turn in the waiting-room, he had filled the bottom of a cuspadore to the depth of two inches with blood coagula. Despite his powerful physique—he was tall, and weighed about two hundred and fifty pounds—he showed signs of great weakness, was pale and exsanguinated, and breathed with difficulty through the mouth, the nose, from which blood rapidly dripped, being stopped up with clots. I seated him and packed his nasal cavity with absorbent-cotton pledgets, squeezed dry of carbolized solution, but without avail. The blood oozed through the firm packing. I removed the cotton, made him blow out the blood-clots, and introduced Goodwillie's nasal speculum, but failed to recognize the source of the hemorrhage, owing to the impossibility of wiping away the blood as rapidly as it welled up from the deeper recesses. What I did recognize, however, was the fact, that the man was rapidly growing weaker, and that he was in imminent danger of falling from the chair in a swoon. There was but one thing to do, and that was to cork up his nasal passages, anteriorly and posteriorly, without loss of time. I had no Bellocq's cannula, however, and there was no time to procure one. In this predicament I bethought me of a simple substitute for the Bellocq, which served me so well that the hope that it may render the same service to others, under the same embarrassing circumstances, must be my excuse for presenting this account of an otherwise very uninteresting experience. I had some rubber drainage-tubing, of assorted sizes, on hand, from which I selected a piece of small calibre, but of sufficient resiliency, about the thickness of a parlor match, and about ten inches in length. One end of this I introduced into the right nasal cavity, and pushed it along the floor of the inferior meatus, through the clots, until it reached the pharynx, whence it curled forward within easy reach of forceps, by which it was drawn out at the mouth, meeting the other end projecting from the nose. The subsequent steps were similar to those employed after the passing of the Bellocq cannula. To the mouth end of the tubing I attached a small, compact wad of elastic lamb's-wool, rolled in iodoform gauze, and, drawing upon the nasal end, I slipped the wad into the post-pharyngeal space and stretched the tubing until the cessation of all trickling of blood down the post-pharyngeal wall showed that the post-nasal aperture was occluded. Still keeping the tubing tightly drawn to its fullest extent, I rapidly packed the anterior nasal recesses with long strips of iodoform gauze to just within the nostril, all around the tubing. I now tied a knot in the rubber, close to its exit at the nostril, and through it passed a crosspiece of tubing of somewhat larger calibre, just long enough to fit easily inside the nostril. Finally, releasing the end of the rubber, its elasticity caused it to fly back, so that the knot and cross-piece rested upon and firmly held in place the anterior gauze-packing. The nasal cavities were thus firmly occluded at both outlets, without any external evidence of the tampon, or any unsightly bulging of the soft parts of the nose. The elastic tubing was at just a sufficient tension to support the packing without the least discomfort to the patient. After forty-eight hours hours it was easily removed, without recurrence of the hemorrhage, by slightly drawing the knot out of the nostril and cutting the tubing just behind it.

UNUSUAL MECHANISM IN SHOULDER DELIVERY.

Dr. James L. Kortright, of Brooklyn, reports the following case: Mrs. L——, aged twenty-two, multipara was delivered February 28, 1890, of a large male child. The only point of interest was in the birth of the shoulders. After the head was born, restitution took place, with the child's face looking toward the maternal right thigh, as is normal in first position of vertex. The anterior shoulder lodged above the symphysis pubis. Delivery was finally effected by the anterior shoulder rotating into the hollow of the sacrum and the posterior and lower shoulder passing under the pubic arch, so that the child's body made a complete semi-revolution and the face at last looked toward the maternal left thigh. In the revolution the face turned toward the bed.

There was recently raised, in this city, a question in connection with fees demanded for filling out death certificates in cases where litigation is a possibility. A patient died in the Bloomingdale Insane Hospital on whose life there was $20,000 insurance. The physicians of the asylum, it is said, refused to sign the certificates unless paid one-half of one per cent. of the insurance.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, April 19, 1890.

THE LANGUAGE OF SCIENCE.

IT is not at all unlikely that an attempt will be made at the approaching Berlin Congress to secure the adoption of one language as the medium of communication in international scientific assemblies such as that will be, or at least that steps will be taken to consider the advisability of such a change. The Volapükists will doubtless be on hand to urge the claims of their step-mother tongue, and others will bring forward each his own native speech as the one best suited to the requirements of a universal language. The French have already put in a claim, for the question was discussed at some length, a year or so ago, in several of their societies, the conclusion of all being that there was no living tongue so universally understood in the world of science as well as in that of diplomacy and in that of society as the French, and therefore that should be adopted by all who met to discuss scientific subjects. In a little pamphlet recently published in this city,[1] English is offered to the world as the one language which, by reason of its simplicity and of its present wide diffusion, is destined to be the language of the future. But there is one obstacle in the way of its universal adoption, and that is the English orthography. The grammar is simplicity itself, the vocabulary is not difficult to any European, but the pronunciation and the spelling are like an ill-mated pair, always quarrelling and always opposing each other. To harmonize these two is the task which the author of this pamphlet has proposed to himself. But like Cinderella's sisters, he so deforms the foot in his effort to make it fit the slipper, that Prince Science would think twice before accepting such a muti lated bride. The author, as he tells us, is a foreigner, and we might have guessed as much, for no one whose privilege it is to possess the English tongue as his own by right of birth would have the heart to so distort it for the sake of others. It is because we love our tongue that we object to its mutilation or caricature, and we have no desire to see its general adoption as the language of science. We can imagine no greater torture than to be forced to attend an international congress in which all the foreign members were trying to speak English, and we were trying to understand them. We confess that we love the English speech too much willingly to see it suffer at the hands, or rather in the mouths, of strangers who bear it no affection, and employ it only as a useful servant, and not as one of the family. There is no language which is so well adapted to the purpose as Latin, and if it is necessary to have this but one tongue, let it be Latin. It has the advantage of being a dead language, and so long dead that there would be few mourners to grieve over the horrible mispronunciation and other abuse that would doubtless be heaped upon it.

[1] Sound English, a Language for the World. By Augustin Knoflach. New York: G. E. Stechert. 1890.

THE FEAR OF THE CORONER.

THERE is a curiously exaggerated notion among ignorant people as to the importance and dignity of the coroner, and it is seldom that anyone can be found who is bold enough or rash enough to touch the body of one who has met with sudden or violent death until the coroner or his deputy has "viewed the remains." This is doubtless well enough when the person is actually dead, but it is carrying it a little too far when, as actually happened the other day in Brooklyn, it operates to prevent the saving of life. Not long ago a young girl was found by her aunt hanging from the rafters of an out-house. When first seen she was still alive and struggling fearfully. Her aunt was too frightened to do anything but scream, and some of the women neighbors who were attracted to the scene actually prevented one of their number from cutting the poor girl down, saying that she could not be touched until the coroner gave permission. When the latter finally came the girl was dead. The coroner is always an object of dread and fear to these poor folks, but that this fear of him should lead a number of women to make not the least effort to save the life of one of their friends dying before their very eyes, is something almost incredible.

THE TOPICAL TREATMENT OF DIPHTHERIA.

THE question of the propriety of interfering in any way with the diphtheritic membrane is one of the many as yet unsettled points in therapeutics. There are still many who regard any attempt to lessen the amount of the membrane by topical applications as injudicious in the extreme; yet the tendency seems at the present time, under the influence doubtless of the microbic theory, to return to local treatment. We do not propose to review the subject of the topical treatment of diphtheria, or even to give a list of the numerous substances that have from time to time been employed in the hope of dissolving the false membrane. We desire only to direct attention to the use of pure salicylic acid for this purpose, as has been proposed by Dr. A. W. Nelson, of New London, Conn., who reports in the *Journal of the American Medical Association* a few cases successfully treated in this way. He applied powdered salicylic acid to the membrane, when the latter was accessible, and believed that he had had good results therefrom. The powder in some instances caused a little stinging pain at first, but this almost invariably disappeared after the use of the remedy had been persevered in for a time. Where the remedy was applied the membrane seemed to become thin and finally to disappear, returning again if the applications were too early discontinued. No irritation was produced to the healthy tissues beyond the slight smarting when the acid was first used. Dr. Nelson regards the remedy as superior to iron applications, as the latter harden the

membrane, while the former acts as a real solvent, and at the same time as an efficient antiseptic. It would seem to be worth a more extended trial than the author has yet given it.

BOYCOTTING THE INTERNATIONAL MEDICAL CONGRESS.

While the medical journals of England, America, Germany, Austria, Italy, Scandinavia and other countries are freely and gladly publishing accounts of the coming International Medical Congress at Berlin, the French medical journals are almost completely silent on the subject. We observe very few French names upon the lists of authors of papers, and, altogether, it looks as though the Doctors of France intended to "boycott" the International Medical Congress simply because it is to be held in Berlin, Such action would be most unworthy of the members of a liberal and learned profession, and would eventually do the French school serious harm in the eyes of the world.

NEW SCHEMES FOR PRELIMINARY EDUCATION.

Our esteemed contemporary, *The American Lancet*, which wreaks itself monthly in editorial interrogatories, has broken all previous records. A leader in the April issue has the following title: "Which shall it be: Three Years' Scientific Study before Beginning the Study of Medicine, Three Years' Scientific Study, Blended with Three Years' Medical Study, or the Equivalent to a Degree of Bachelor of Arts, before entering upon Medical Study?"

We learn that this tremendous aggregation of querying alternatives is based upon a report that the Faculty of Michigan University has been considering at several meetings the requirements of the medical course at the University. It appears that all parties grant the necessity of increasing the preliminary requirements of students entering the medical department.

The professors of the literary department desire that a preparation of about three years of scientific study be pursued in the literary department before the student can enter upon the medical course. Then, at the end of three years' medical course, the student be given two degrees—a M.S. and an M.D.

The second plan is from the Medical Faculty, who wish the students to carry during six years the studies of both the literary and medical departments, making a six years' course.

A third plan is being agitated that renders the degree of Bachelor of Arts necessary for entering upon the study of medicine. At this date it is not known which plan will prevail, but we join heartly with *The American Lancet* in hoping that some progressive action will be taken.

The Medical Society of the Missouri Valley.—A member of this Society writes that the meeting in St. Joseph, on March 20th and 22d, to which we referred in a recent issue, was the regular quarterly meeting, the Society having been organized over a year ago at Council Bluffs, Ia. The Association is in a very flourishing condition, having now a membership of over two hundred.

News of the Week.

The St. Louis Post-Graduate Medical School has gone out of existence as a separate institution, having become amalgamated with the Missouri Medical College. The collegiate course in the latter school has been lengthened to three years.

Nursery and Child's Hospital.—The position of assistant physician at the country branch of this hospital will be filled by competitive examination on May 15th There is a salary of $500 attached to the position.

The New York Post-Graduate School has received a bequest of $10,000 by the will of the late Senator St. John.

New Reception Hospitals for Upper New York.—The State Senate has passed a bill "for maintaining suitable places and wards for medical and surgical treatment of persons injured or taken ill north of the Harlem River, and south of 175th Street.

The State Care of the Insane Bill was signed by the Governor on April 15th, and is now a law. By the terms of the act all of the pauper and indigent insane in all the counties of the State, except New York, Kings, and Monroe, will be cared for and maintained by the State without any charge or expense whatever to the counties. The number of insane affected by this bill is a little less than 2,300, less than one-half of the whole number now cared for by the State. No asylums are to be built, as the State had before the passage of the bill adopted plans for, and entered upon the construction of, buildings in which 1,600 of the number to be cared for can be accommodated, leaving only 700 to be provided for by the erection of small detached buildings on the grounds of the present State asylums, at a cost of $550 per patient, or $385,000 for the whole number. Hereafter no pauper or indigent insane person can be returned from a State asylum to a county asylum.

The Pasteur Institute.—The New York Pasteur Institute was opened on February 18th, and from that date to March 31st thirty people applied for relief. Of these 9 were treated, and are at present in good health. In 3 cases hydrophobia was shown to exist by the results of inoculation of other animals with the spinal cord of the rabid dogs. Four of the patients were from New York City, 3 from Long Island, and 1 each from Maryland and Arkansas. The Institute is located at 178 West Tenth Street.

Brooklyn to be Sued by Physicians.—Twenty-two physicians who were employed on the summer vaccinating corps by the Brooklyn Health Commissioner, and who have not been paid for their services, have hired lawyers and had claims filed preparatory to suing the city. They have not been paid because the Civil Service Commission said they were irregularly employed. Commissioner Griffin employed them in an emergency, believing that he had full power to do so. There is no question as to the performance of the work charged for. The amount of the claim in each case is $120.

Cavaliere V. Capecchi, one of the leading Italian alienists, died at Florence in February last, aged eighty-eight.

The Late Sir William Gull left a fortune of over a million and a half of dollars.

Medical College Commencements.—Fort Wayne Medical College, March 11th, 7 graduates. Beaumont Medical College, March 20th, 23 graduates. Central College of Physicians and Surgeons, Indiana, 8 graduates. Medical College of Indiana, 28 graduates. Western Reserve University, Cleveland, O., March 5th, 30 graduates. Atlantic Medical College, 51 graduates. Southern Medical College, March 5th, 33 graduates.

The Alleged New Disease, "La Nona," which has been reported to be prevalent in Italy, is said not to be anything new at all. The cases on which the report was based were probably those of some peculiar results of the "grip."

Catholics and Cremation.—The Archbishop of Paris has informed the *curés* of his diocese that the Pope has forbidden Catholics to cremate their dead, or to belong to cremation societies. Catholic priests are therefore directed to refuse the usual rites when bodies are burnt.

Medicine not an Intellectual Profession.—The New York *Herald* publishes on Sundays articles from the pens of various medical men of different degrees of celebrity. Its last contribution, which was on the subject of heads and skulls, concluded with the statement that medicine was, as an intellectual calling, far inferior to the law, and that a body of lawyers presented a much more intelligent and intellectual appearance than a body of physicians. Will not some of our readers come to the defence of his calling? We recall Mr. Philip Gilbert Hamilton's interesting dissertation on the doctor, in his "Intellectual Life." Mr. Hamilton was kind enough to place the physician quite high in the ranks of intellectual workers.

The Brooklyn Homœopathic Hospital, situated on Cumberland Street near Myrtle Avenue, has recently been completed. It has a capacity of one hundred and thirty-five beds.

The Babies' Hospital, at the corner of Lexington Avenue and Fifty-fifth Street, is in a very prosperous condition. During a recent visit to the institution we were pleased to note the cleanly and admirable arrangements for the care of the little ones. Under the management of a ladies board, of which Mrs. Andrew H. Smith is the president, nothing is left undone to make it a model institution of its kind. There are at present twenty-two inmates, ranging from a few months to four years of age. The hospital is in need of funds from the charitable, and no more worthy object for contributions can be named in connection with the care of the really sick and needy.

Justice to Hospital Graduates.—Dr. R. Ellis, of Danbury, Conn., writes: "The MEDICAL RECORD of April 5th contains an article headed 'Justice to Hospital Graduates.' I am very certain many medical men will oppose the plan of adorning the names of hospital graduates with the title of H.G. Medical men very well know that titles do not necessarily mean ability; in fact, the possessing of degrees is so common and so easily obtainable that our best medical men sign themselves simply M.D. It is safe to say that not one physician in ten has served as hospital interne. Are the other nine inferior to him? Not necessarily. Several have taken post-graduate courses at home or abroad, and are acknowledged to be better practitioners than our hospital graduate (H.G.). Then why not give them the degree of P.G.G. (Post-graduate-graduate)? And here is the last man of the ten, who possesses neither capital nor environment, but by hard study and attendance at clinics, etc., he has made himself, as his future shows, the best practitioner of all. Why not give him the degree of C.G. (Clinic Graduate)? Medicine has to-day so differentiated that a hundred paths lie open to a graduate in medicine, of which the hospital is one. Why favor this class with an unnecessary title? Hospital graduates daily meet non-hospital men who are greatly their superiors. Let our colleges and medical schools give degrees gained only by hard work, and let the matter end there, else our medical men will be labelled thus: H. Hawthorn Blowhorn, A.B. (Yale); M.D. (Harvard); H.G.M.S. (Presbyterian Hospital Graduate Medical and Surgical); P.S.K. (Pathologist Student under Koch); P.G.S.B.P. (Post Graduate Student, Berlin, Paris); P.E.W. (Prize Essay Writer)".

Medicine and Politics.—Among the jobs defeated in the Maryland Legislature, says *The Civil Service Reformer*, was an attempt to increase the number of managers of the State Insane Asylum with a view to obtaining a majority willing to turn out the efficient and able Superintendent, Dr. Gundry, and provide a place for a politician. The only reason suggested for the proposed change was that Dr. Gundry was a Republican. No more barefaced piece of spoilsmongering than this could be conceived, and its failure is a cause for congratulation.

Death from Bromide of Ethyl.—A somewhat important case is now before the Berlin courts, in which a dentist is charged with having caused the death of a patient by means of an anæsthetic. The patient was a lady, and the dentist entrusted his pupil, whose age was under seventeen, with the administration of bromide of ethyl. Of this about an ounce was administered, together with four of five drops of chloroform. The patient is stated to have recovered completely from the effects of the anæsthetic, and to have felt quite well during the remainder of the day. The next day, however, she died, and a commission of medical experts has been directed to report upon the matter.—*The Lancet.*

Mr. Gladstone's Head is said by his English Liberal admirers to be growing larger. The same legend states that Napoleon's head increased in size up to the age of forty-five. The stories are both preposterous and impossible. After thirty, at the latest, the head only grows larger from bony disease.

Leprosy in Indiana.—The newspapers report that there are two well-defined cases of leprosy near English, Ind. The patients are father and son.

A Physician Sues a Temperance Advocate.—Dr. F. A. Barnett, of Lebanon Junction, Ky., has sued the editor of a temperance journal for libel on account of an article charging him with trafficking in liquor under the guise of prescribing it for his patients. The doctor denies these statements, and charges that they were maliciously made. He denounces the statements as false and libellous, and asks to be awarded a judgment for ten thousand dollars for the damage which he has sustained in his church and his profession by reason of the publication.

Fever Thermometers.—We once reported the case of a man who swallowed his fever thermometer, mistaking it for a pharmaceutical compound. The *Northwestern Lancet* chronicles some misconceptions of this instrument almost equally great. It says: Fever thermometers are not generally supposed to be difficult instruments to handle, but that there are some physicians who are a little mixed about the ends of the thermometer, if not of the patient, is shown by the following letter accompanying an order for a fever thermometer upon leading St. Paul dealers in surgical instruments:

"*Dear Sirs:* As there is some dispute among doctors as to the use of clinical thermometers, will you please tell me: 1st. Do you place the bulb or the end that contains the mercury in the mouth or the other end? 2d. If so, is there any kind made where you place the other end in the mouth? If you will answer me you will oblige."

Money for the Talk.—An Irish physician was called to see an Irish woman, but prescribed no medicine. The woman objected, and, when he asked for his fee, she answered, "Be jabbers, and for phwat?" His quick reply was, "Faith, and for the talk I gin ye."

New York Infant Asylum.—Dr. George T. Elliott has been appointed Dermatologist, and Dr. W. R. Townsend Orthopædic Surgeon to the New York Infant Asylum, located at Sixty-first Street and Tenth Avenue, and Mount Vernon, N. Y.

Dr. Herbert W. Moorehouse, of Danville, Ill., has been appointed chief surgeon of the Wabash Railroad system.

Charges against an Insane Asylum Management.—A Pittsburg daily paper has brought charges of cruelty against the management of the Western Pennsylvania Hospital for the Insane at Dixmont, which, it is said, will result in a legislative investigation.

A Death under Chloroform occurred on March 26th in Columbus, O. The patient was a man, fifty-six years old, who had been thrown from a wagon and sustained a fracture of the thigh. Chloroform was given preliminary to a reduction of the fracture, but death took place before the operation was begun.

Dissecting Material Scarce in Kentucky.—A party of Louisville grave robbers was recently interrupted in an attempt to obtain bodies from the cemetery at Anchorage, near that city. This is the second time that such a party has been apprehended recently. It is said that Kentucky and Georgia are the only two States in the Union that have not a law giving to the medical schools the dead bodies of paupers which are not claimed by friends, and an effort is being made to have such a law passed by the Kentucky legislature.

Removal of a Large Portion of the Stomach with Gastro-enterostomy was successfully performed April 10th, at the New York Hospital, by Dr. W. T. Bull. The patient was a woman, twenty-nine years of age, who had suffered for several months with nausea, occasional vomiting, and epigastric pain. She had lost much flesh, and a tumor of the size and shape of the kidney was plainly felt halfway between the ensiform appendix and umbilicus. On opening the abdomen by a median incision, an ovoid carcinomatous tumor was found to involve the greater curvature and posterior wall, extending from the pylorus, a distance of five or six inches outward. After ligating the gastro-hepatic and gastro-colic omentum, the tumor was removed, together with the pylorus, and about one-quarter or one-third of the pyloric end of the stomach. The cut end of the duodenum was then sutured so as to form a blind pouch, the stomach likewise treated, and an anastomosis made with the jejunum near its commencement, by means of Abbe's catgut rings. The operation lasted three hours and a half. There was a serious fear of prostration at the end of the second hour, but at its close the patient rallied. All food by the mouth was withheld till the fourth day. There have been no untoward symptoms whatever, and the temperature and pulse on the seventh day are normal; liquid food has been taken freely and the bowels have moved spontaneously.

Attempt to Burn a Hospital.—An insane patient confined in the Montevue Hospital, in Frederick, Md., attempted to set fire to the building recently. He scraped the plastering off the partition wall in his room with a spoon, and, pulling out several laths, broke them into kindling wood. Forcing the door, he seized a lantern hanging in the hall, and with it ignited the kindling. The smoke soon filled the corridors, and in this way the fire was discovered before it had done any damage.

Obituary.

PROFESSOR HENRY H. SMITH,

PHILADELPHIA, PA.

Professor Henry H. Smith died at his residence in Philadelphia, on April 11th, aged seventy-four. Professor Smith was a well-known surgeon, and his contributions to medical and surgical science gave him a distinguished position in the profession. He was born in Philadelphia, December 10, 1815, and studied medicine with Professor W. E. Horner, graduating from the University of Pennsylvania in 1837. The two years following he visited London, Paris, and Vienna, and made a study of the hospital systems in those cities. He returned in 1841, and instructed private classes in surgery.

At the beginning of the Civil War he was appointed to organize the Hospital Department of Pennsylvania, and at the same time was made Surgeon-General of Pennsylvania. In this capacity he contributed much to the efficiency of the medical service of the Pennsylvania Reserve and other State regiments. At the first battle of Winchester, Va., he originated the plan of removing the wounded from the battle-field to large hospitals in Reading, Philadelphia, Harrisburg, and other cities, and established the custom of embalming the dead on the battle-ground.

He organized and directed a corps of surgeons, with steamers as floating hospitals, at the siege of Yorktown, and served the wounded after the battles of Williamsburg, West Point, Fair Oaks, Cold Harbor, and Antietam. After thoroughly organizing the department of which he was in charge, he resigned his commission in 1882, and was since actively engaged in the practice of his profession.

He wrote and published several works on surgery, among them being an "Anatomical Atlas to Minor Surgery," which was republished four times. He was also the author of a "System of Operative Surgery," "Practice of Surgery," and a number of medical works, which have received high praise.

He was surgeon at the Episcopal and St. Joseph's Hospitals, and the Blockley Almshouse, and in 1855 he was Professor of Surgery in the University of Pennsylvania.

Reviews and Notices of Books.

History and Pathology of Vaccination: A Critical Inquiry. By Edgar M. Crookshank, M.D., Professor of Comparative Pathology and Bacteriology in, and Fellow of King's College, London. Philadelphia: P. Blakiston, Son & Co. 1889.

Professor Crookshank has accumulated a vast amount of instructive, suggestive, and interesting matter upon the above subject, and has presented it in two handsome volumes. In order to clearly state the author's views we quote from page 463, Vol. I.: "As the result of an investigation into the history, and especially the pathology of vaccination, I feel convinced that the profession has been misled by Jenner, Baron, the reports of the National Vaccine Establishment, and by a want of knowledge concerning the nature of cow-pox, horse-pox, and other sources of vaccine lymph. Though in this country vaccine lymph is generally taken to mean the virus of cow-pox, yet the pathology of this disease and its nature and affinities have not been made the subject of practical study for nearly half a century. We have submitted instead to purely theoretical teaching, and have been led to regard vaccination as inoculation of the human subject with the virus of a benign disease of the cow, whereas the viruses in use have been derived from several distinct and severe diseases in different animals." Again, on page 464, Vol. I. may be found these statements: "Jenner's substitution of cow-pox inoculation (for small-pox inoculation) was a purely empirical treatment, based upon folk lore, and involved a totally different pathological principle—the protection from one disease by the artificial induction of a totally distinct disease—a principle which was not, and has not been since, supported by either clinical experience or pathological experiments."

Then comes an assertion which will surprise some of our readers, namely: "Inoculation of cow-pox does not have the least effect in affording immunity from the analogous disease in man, syphilis, and neither do cow-pox, horse-pox, sheep-pox, cattle-plague, or any other radically dissimilar disease, exercise any specific protective power against human small-pox." In order to support these allegations he furnishes evidence obtained from letters and statistical papers, prepared by men, professional and non-professional, who were contemporaneous with Dr. Edward Jenner, and it will amply repay any inquirer after the truth to study most carefully these various letters and papers, to satisfy the questionings of his own mind with reference to the conclusions arrived at by Professor Crookshank. Birch's reasons for objecting to the practice of vaccination are quoted in extenso. He says: "Can anyone disprove the three following: That vaccination has been too often fatal; that vaccination has introduced new disorders into the human system; that vaccination is not a perfect security against the small-pox?" He further states that the Jennerian committee confessed that many cases of inoculation with cow-pox virus developed subsequently the small-pox. Attention is likewise called to the fact that not a few milkers who acquired cow-pox accidentally became infected with small pox afterward when exposed to its contagium. The following conspicuous case is reported in support of the above theories and assertions. In 1811 Jenner was called to London because of the development in the person of the Hon. Robert Grosvenor of a violent attack of small-pox, he having been ten years previously inoculated with the cow-pox by Jenner himself.

On the other hand, there is considerable testimony which leads us to discredit in large measure the above and believe that vaccination does protect against small-pox. Woodville is quoted as saying: "It has been asserted that persons have had the small-pox after having been affected with the cow-pox, and some facts have been published with a view to show that instances of this kind have actually happened. But all these, as far as I have seen, have been very defective in not affording sufficient proof that the affection, supposed to have been the cow-pox, was in reality that disease. On the other hand, the instances which have been brought forward to prove that those who had undergone the genuine cow-pox resisted the infection of the small-pox are unquestionably decisive, and sufficiently numerous to establish the fact in the most satisfactory manner. This circumstance, then, appears to be as much a general law of the system as that a person having had the small-pox is thereby rendered unsusceptible of receiving the disease a second time." Thus, much may be said on both sides, although the unprejudiced and impartial critic will incline to the opinion that insufficient proof has as yet been given of the inefficiency of vaccination. Professor Crookshank has, however, placed the profession under great obligation to him for furnishing them with such a mass of unusually interesting and helpful literature upon a subject about which physicians should have greater knowledge. These books are specially interesting, because they contain the fac-simile of an unpublished letter from Jenner to Mr. Head, and a fac-simile of the first folio of the manuscript of Jenner's original paper. There are also beautifully colored plates, showing casual cow pox, natural horse-pox, inoculated syphilis, variolation of the cow, phagedænic ulceration in natural cow-pox, natural horse-pox simulating aphthous stomatitis, and roseola of cow-pox.

A Text book of Physiology. By M. Foster, M.A., M.D., LL.D., F.R.S. Fifth edition. Part II., Book II. 8vo, p. 846. London & New York: Macmillan Co. 1889.

The present volume, being Part II. of the fifth edition of this classic work, treats of some of the most important apparatus of the human body, and is consequently invested with great interest to the practitioner. The tissues and mechanism of digestion are first considered, with their proximate and ultimate bearings on nutrition and are arranged for consideration under the headings of saliva, gastric juice, bile, pancreatic secretion, succus entericus, the lymphatic system, respiration, urinary secretion, sweat, animal heat, and diet.

Covering such a wide range of subjects within a comparatively small compass we have, however, presented to the reader the essential and salient points for a thorough comprehension of the complex phenomena of tissue metamorphosis and its bearing upon nutrition. The relations of the different functions to each other and their interdependencies are systematically treated and leave nothing to be desired for the earnest student who wishes to keep abreast of the present advanced state of the science. The style is terse and perspicuous and gives an extra force to convictions based upon wide and varied experimentation.

Diseases of Women and Abdominal Surgery. By Lawson Tait, F.R.C.S. Edin. and Eng., LL.D., etc. Vol. I., pp. viii., 547. Philadelphia: Lea Brothers & Co. 1889.

The appearance of this, the most elaborate of Mr. Tait's literary productions, increases our admiration for the tireless worker whose busy pen keeps pace with his phenomenal activity in abdominal surgery. We are prepared for a somewhat aggressive tone in this volume, nor are we disappointed. The preface is itself a challenge to "the old-fashioned mechanical school, the teaching of the speculum, the sound, the caustic stick, and the pessary," which, as the author confidently remarks, "has been practically killed." Other remarkable statements appear in the preface, among which we read that "gynecology and obstetrics are now happily (?) severed, and this division of labor has resulted in enormous advances for both." In short, the reader would naturally infer from this introduction, that outside of abdominal surgery there is little in the treatment, of diseases of women which de-

serves more than a passing notice. We submit that this is a most unfortunate prelude for a work which is commended to the profession as the latest authority on gynecology, and the author must not be surprised at the criticism which he manifestly invites.

The wide scope of the work is indicated by the "table of the organs concerned," in which are included under no less than twelve heads some structures which can hardly be regarded as "organs," viz.: The "mons veneris, vulva, vagina, urinary tract, uterus, broad ligaments and mesentery, Fallopian tubes, ovaries, pelvic bones, liver and gall-bladder, kidneys, spleen, and pancreas, colon, rectum, cæcum and small intestines, and breast." So far as we can determine, without the aid of a much-needed table of contents, the present volume alone deals with affections of the pelvic organs, and is practically a combination of the author's earlier work on diseases of women and his more recent monograph on diseases of the ovaries, with such omissions and additions as would be expected from a writer of his progressive tendencies. Pathology, diagnosis, and treatment are sadly jumbled together, but out of the heterogeneous mass the reader can extract numerous original and valuable suggestions, such as cannot be found elsewhere. In the opening chapter, upon diseases of the external genitals, we note several pages on the clitoris, in which the author takes occasion to make a kind and generous apology for the error of Baker Brown, whose severe treatment at the hands of his professional brethren was certainly "a matter of regret."

No American gynecologist can approve of Mr. Tait's strong statements on the subject of pelvic examination. They are certainly not calculated to aid the beginner. When we read that the bimanual method is never required except for the diagnosis of disease of the uterine appendages, and that "in the great majority of instances even here, in the case of the experienced gynecologist," it is "unnecessary," we cannot but feel that serious errors can hardly be avoided by the less experienced, who would venture to open the abdominal cavity on the strength of such a superficial examination. "If a man cannot do his work with Ferguson's speculum, occasionally replaced by the duck-bill, he ought to give it up. A workman who needs complicated tools is an inefficient one or a quack." This is rather hard on some of us who follow the teachings of Sims and yet dislike to be included under the latter category. The brief section on the urethra and bladder is so superficial that its omission would have been desirable.

Chapter IV., on the uterus, is remarkably comprehensive—and unsystematic. One can only infer after a review of the ten pages on displacements that non-surgical gynecology is *not* the author's strong point. According to his view, there has been no advance in the study of displacements since 1848. "I hate pessaries," he frankly admits, "and I never use them if I can help it." We would hate them too if we were limited to the instruments which he figures. There are a few others, thank heaven! "Nothing more useless than Emmet's operation has ever been introduced into surgical practice," is another compliment, more vigorous than courteous, which our author pays to his American friend. So-called laceration of the cervix is only an "innocent fissure," the repair of which can have no influence upon subinvolution, Mr. Tait's "routine treatment for which, and all its complications for the last eighteen years, has been chlorate of potash, five grains thrice daily, ergot to be added during, and for two or three days before, menstruation." Ninety per cent. (!) of his patients are cured by this beautifully simple treatment.

After presenting at length his statistics showing the results of the operative treatment of fibro-myoma, the author dismisses with a few contemptuous expressions the claims of Apostoli and his followers, making no mention of the honest work of Keith, whose reputation for accuracy of observation and, above all, for veracity will certainly outlast that of his Birmingham *confrères*.

With Chapter V. we plunge into abdominal surgery—a thrice-told tale—with a suddenness which indicates how little interest the author feels in minor surgical gynecology and how willingly he turns to a nobler theme. We need not review this portion of the book, since the reader is already sufficiently familiar with the subject matter, and especially with the statistics, which have not been as a "candle put under a bushel." They have already been allowed to speak for themselves—early and often. Whenever the name of any authority who ventures to differ from Mr. Tait is mentioned, it is in terms which are strong, not to say abusive.

As we intimated at the outset, it is difficult to characterize such a work as the one under consideration. Every page abounds in contradictions. Side by side with bright, original thoughts are the most reckless, discourteous criticisms of the work of men whom the profession delight to honor. Valuable suggestions in surgery, which the reader willingly accepts as distinct additions to that art, jostle wild pathological theories based entirely upon the author's *ipse dixit*, which reason and common sense alike impel him to reject. Mr. Tait will never be recognized as either a pathologist, or a gynecologist in the true sense of the term. His position in surgery is now clearly defined.

Nothing more can come from his prolific pen which will change our opinion regarding his strong and weak points. For this reason, we do not believe that the present ambitious work will either add to or detract from his reputation.

Syllabus of the Obstetrical Lectures in the Medical Department of the University of Pennsylvania. By Richard C. Morris, A.M., M.D., Demonstrator of Obstetrics, University of Pennsylvania. Pp. 154. Philadelphia: W. B. Saunders.

This modest little compend is so far superior to others on the same subject which have previously appeared that we take pleasure in calling attention briefly to its excellent features. Small as it is, it covers the subject thoroughly, and will prove invaluable to both the student and the practitioner as a means of fixing in a clear and concise form the knowledge derived from a perusal of the larger text-books. The author deserves great credit for the manner in which he has performed his work, which he modestly terms a compilation. He has introduced a number of valuable hints which would only occur to one who was himself an experienced teacher of obstetrics. The subject matter is clear, forcible, and modern. We are especially pleased with the portion devoted to the practical duties of the accoucheur, the puerperium, care of the child, etc.

The paragraphs on antiseptics are admirable; there is no doubtful tone in the directions given. No details, however insignificant, are regarded as unimportant. For example, the exact number of articles in the baby-basket, the precise amount and character of the nourishment to be given to the infant from week to week, the care of the nipple—none of these minor matters is omitted. We venture to say that even the old practitioner will find useful hints in this direction which he cannot afford to despise. We are happy to add that the book is not designed as a short cut to "cramming" for examination. It would be well if this practice were discouraged in New York by inauguarating such a method of practical examinations that it would be impossible.

The Emperor of Germany's Ear.—It is said that the Emperor of Germany is again troubled with his otitis, and to such an extent as to deprive him, on account of pain, of much sleep. The discharge is quite profuse, necessitating the use of a cotton plug. The continuance of such a condition is fraught with grave apprehension, and may necessitate operative interference.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 20, 1890.

ALFRED L. LOOMIS, M.D., PRESIDENT, IN THE CHAIR.

The Use of Physicians' Names by Manufacturers in Advertising.—DR. A. JACOBI rose to a question of privilege, and stated that the firm of Eimer & Amend, who manufactured Seibert's apparatus for the sterilization of milk in artificial infant-feeding, had refused to heed his request, although his letter had been honored by Dr. Seibert, to erase his name from the circular distributed with this apparatus. It was his position that every article of merchandise must stand upon its own merits, and in making this public announcement in condemnation of the course adopted by the firm mentioned, he hoped it would serve as a warning to others.

The Relation of Peripheral Irritation to Diseases.—Such was the general subject for discussion, several phases of which were taken up by different authors.

The Relation of Ocular Irritation.—DR. D. B. ST. JOHN ROOSA read a paper with this title (see p. 429).

The Relation of Naso-Pharyngeal Irritation.—DR. BEVERLEY ROBINSON treated of this phase of the subject (see p. 434).

The Relation of Reflex Neuroses.—DR. M. ALLEN STARR read a paper on this phase of the subject. The active part of the nervous system was the gray matter; the white matter merely carried impulses to and from it. This gray matter was collected in three quite distinct masses—the spinal and medullary centres, the basal ganglia, and the cortex. In the entire vertebrate species it was possible to assign to these distinct masses different functions: to the spinal and medullary centres, reflex action; to the basal ganglia, automatic action; to the cortex, conscious and voluntary action. In dealing with reflex disturbance it would, therefore, at first appear that we were to be limited in our discussion to affections of the spinal cord and medullary centres. These must certainly be considered, but we were not thus limited, for each lower system was under constant control of the one above it. Hence disturbance of reflex action might be brought about by anything which either increased the normal inhibitory action of the higher centres or removed that action, as well as by disease of the reflex centres themselves. Examples of reflex activity were seen in sneezing, winking, swallowing, coughing, vomiting, flushing of the skin when exposed to changes of temperature, regular respiratory and cardiac movements, vascular tone, besides so-called tendon and skin reflexes. Without such reflex action the balance of supply and demand in the human economy would be impossible and life would cease. A power of quick and appropriate response to normal or abnormal irritation was a natural power of the lowest masses of gray matter, and he was unable to find any evidence from the study of disease that the exercise of this power was in any way detrimental, or that any over-action of these reflexes was harmful.

This power might be interfered with in several ways, as by certain drugs, by meningitis, traumatism, etc. But the reflex mechanism was too important and too stable to be affected by little irritants, otherwise life would be put in constant danger.

Turning to other causes of disturbance of reflex function than different forms of irritation, they existed in defective control by higher centres. The act of control must be constantly exerted in order to preserve the balance of power and the proper harmony of action in the nervous system. A slight defect in central control produced wide-spread and serious results. In diseases known as reflex neuroses, in which there was no real defect in reflex action, but only an undue or inharmonious reflex activity, the actual origin of the disease must be either in an excess of activity in the lower centres, or a defect of control in the higher centres. Now, it had been shown that an excess of activity was commonly called forth only by very severe causes; while a defective control might come from slight ones. It was his opinion that, in the various reflex neuroses in which peripheral irritation was the actual cause, nature indicated that fact by attracting attention to the seat of irritation by discomfort and pain. And when, as in very many cases, the source of irritation was by no means evident, was only found, or supposed to be found, by extraordinary effort, the probability was largely in favor of the assumption that the reflex neurosis was not produced by any direct peripheral irritation, but was the manifestation of a slight or serious defect of control by higher centres, due to their impaired nutrition and consequent impaired activity.

In his own experience he was sure that a very large majority of the patients who presented symptoms of reflex neuroses had been exposed to influences which undermined the strength and nutrition of the entire nervous system, were to be regarded as suffering from functional or organic disease of the highest, most complex portion of the nervous system, and were not merely the victims of irritation in some peripheral organ. This view applied to so-called uterine reflex neurosis, to eye-strain, etc. A serious strain of the intra-ocular tension, such as occurred in astigmatism and hypermetropia, gave rise to discomfort, to voluntary effort, to strain the eyes in using, to effects upon, not the centres governing ocular motion, but upon the conscious voluntary centres of the cortex, the centres of highest evolution which were most susceptible to slight effects. The result was cortical exhaustion, similar to that produced by uterine or ovarian pain, or by pain anywhere, or by mental shock or worry. The trouble was not spinal, was not reflex, but was cortical. Thus, while peripheral irritation might produce nervous symptoms, it was not directly through the lower centres, it was not by exciting reflex action, but was rather by producing exhaustion of the highest conscious centres which controlled the entire nervous mechanism. Therefore, in treatment do not be satisfied with merely removing the peripheral irritation, but increase the nutrition of the entire system.

Stability of the Ocular Muscles the Exception.—DR. C. S. BULL discussed Dr. Roosa's paper, with which he agreed in all respects. He also had found that perfect equilibrium of the ocular muscles was seldom present, even in the healthy individual; in fact, in one subject he had found it vary at each of six examinations made during the twenty-four hours. Asthenopia was almost invariably due, in healthy and not over-strained subjects, to some uncorrected error of refraction, in most instances to some form of astigmatism or hypermetropia. He hoped the sad chapter on operations for ocular insufficiency as a cause of reflex diseases had been concluded.

A Middle Ground.—DR. C. C. RICE discussed the second paper, and said he thought Dr. Bosworth was the gentleman who should have a hearing after Dr. Robinson, for it was his views which had been attacked. Perhaps one reason for the difference in frequency of nasal disease in cases of hay fever and asthma, according to whether they were seen by Dr. Robinson and the general practitioner, or by the specialist, as Dr. Bosworth, was the fact that only such patients as had nasal disease usually consulted the rhinologist. In some cases the nasal affection might be chronic and constant, as when a permanent obstruction existed, causing attacks of asthma at any season of the year; in others the nasal symptoms might be manifest only when pollen or other irritant was in the air. The speaker also referred to symptoms referable to the eye and elsewhere, relieved by the treatment directed to the nose.

Further discussion on the subject was postponed until the first meeting in May.

National Association of Railway Surgeons.—This association will meet in Kansas City, Mo., May 1st, and will be in session three days.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, March 7, 1890.

FRANCIS P. KINNICUTT, M.D., PRESIDENT, IN THE CHAIR.

DR. V. P. GIBNEY presented two patients, the first illustrating "Artificial Feet in a case of Arrested Development."

The young lady whose case I present this evening was treated by Dr. James Knight many years ago, and was published by him in his work on "Orthopædia." The notes of the case taken from this book are in substance as follows:

"She was twenty months of age at the time she came under observation. The legs were held flexed upon the thighs, and the thighs upon the abdomen, while the thighs themselves presented an extraordinary degree of development. The length of the legs was about three inches, the feet being of ordinary size, yet having only three toes on each. The distance from the tuber ischii to the posterior extremity of the os calcis measured four inches. There was no appearance of a knee-joint. The ankles had free motion, and the thighs were seemingly movable upon the pelvis. Abduction was apparently normal. A subcutaneous myotomy was done on the posterior aspect of both legs, two inches from the insertion of the muscles into the os calcis. Moderate extension was applied. The deformity yielded slowly, and soon imperfect knee-joints were discovered. A second tenotomy was performed on the leg, and, at the end of another year, by persistent traction, the position of the limbs was so improved that the child could stand erect. The feet were much everted, however, and the Achillis tendons were shortened, so that both feet were in marked valgus. The upper limbs presented arrested development below the elbows, the right limb being much longer than the left. There were rudimentary digits on the right side, a single digit on the left."

The patient gained more use of her limbs as time went on, and for many years it was my privilege to fit her with club-foot shoes. It required pretty nice adjustment to make her at all comfortable, and in 1888 she referred to me for further relief, and I advised her to consult Freese, the artificial limb maker, who fitted her with a pair of artificial feet with which she has been able to get about with much more comfort than she ever did previously. The limbs were thus lengthened sufficiently to give her the present height, that of a woman of medium size, or rather, a little under the medium size. The artificial limbs, you will see, are made so that the natural feet rest in a pair of stirrups fully extended, and to these stirrups the remainder of the apparatus is attached. The facility with which she can use her hands is surprising. She has only this evening entertained me with some music. She writes very legibly, does needlework, and paints.

The second was "A Case of Ostitis Deformans, or Paget's Disease."

This gentleman was referred to me by Dr. Lyon, of Harlem, in January, 1890, for relief of his bow-legs. He is fifty years of age, is a carpenter by occupation. The limbs are markedly bowed, as you can see, the distance between the knees as he stands being six inches—this from skin to skin. The limbs are of equal length. Over each thigh, on the upper and outer aspect, is a mass that seems like a fibrous tumor. It is connected apparently with the tensor vaginæ femoris. These masses are symmetrical, are painless, and increase in size when the muscle is active. There is some laxity of the knee-joint; no pain on handling the limbs. He finds most ease with his legs crossed scissors fashion. His arms are strong, though he thinks they have increased in size. His elbow joints are altered in appearance. The inner condyle of each humerus is quite sharp, and unusually prominent. His head has increased in size, in that he formerly wore a 6¾ inch hat, and now wears a 7½ inch. His disease began apparently about five years ago, without apparent inflammatory signs, and unpreceded by any acute illness. He scarcely knows what sickness is.

The patient this evening complains that he has grown worse since I saw him in January. He is quite unable to get about any distance without a cane; cannot work; feels weaker generally. Certainly the deformity at the knees is much greater. He is quite sure, too, that his head has grown a little larger since my observation.

In 1876, Sir James Paget first drew attention to the disease, and since then numerous cases have been recorded. Mr. J. R. Lunn, in St. Thomas's Hospital Reports for 1883, Volume XIII., gives a full account of the case. He has reported four other cases. The symptoms described by these observers are pains of a rheumatic character in the affected limbs, loss of height in male patients, increased size of the head, rendering their hats too small. Sir James Paget described it as a chronic ostitis. Mr. Lunn's conclusions, however, are that we have: 1. A constitutional disease producing atrophy and absorption of a large part of the osseous system. 2. Consequent weakening of the bones, so that they yield when exposed to strains. 3. Compensatory strengthening of the growth of what may be looked upon as a variety of callus. 4. The occasional formation of definite tumors. 5. Fatal cachexia. Specimens in a fatal case have been shown to Dr. Sharky by Mr. Lunn, and the report is as follows: "The most striking points in sections of the occipital bone are: 1. The irregularity in the anatomical structure of the bone. 2. Absorption or rarefying ostitis appears to be the predominant process, producing very large and very irregular Haversian canals, which produce Howship's lacunæ, as well as much larger indentations in their walls; they are lined by a thin layer of tissue which stains with logwood, as is usually the case in rarefying ostitis. 3. The bone corpuscles are distributed with great irregularity, presenting, for the most part, no arrangement in parallel lines. 4. The bone lacunæ are mostly small, shrunken, and supplied with few processes. 5. There is but little appearance of the natural lamellar arrangement in the walls of the Haversian canals, and where lamellæ are seen they are ill-defined, and many having different directions meet together in the walls of one Haversian canal. 6. There is also clear evidence of a formative ostitis, seen in the reduction of some Haversian canals to the smallest calibre, and in some parts the parallel lamellæ of new bone which have produced this change can be clearly made out. 7. Besides the lines in the walls of the Haversian canals, which are due to their lamellar arrangement, there are others quite irregular in appearance, and consisting of series of curves which cross each other, or else follow more or less the direction of the lamellæ. The nature of these lines is not evident. The portion of the tumor from the ileum which was given me to examine, presented the microscopical characters of cartilage throughout. Nowhere was any sarcomatous tissue seen."

At the Toronto Medical Society, April 30, 1885, Dr. McPhedran presented a case of a female, sixty-three years of age, English, with good family history. She had been ailing since she was forty-five. Six years prior to the date of presentation of the case, she had a severe illness in which the right side was paralyzed. Within a few months she began to complain of pains in the right leg, and soon noticed that it was larger and beginning to bend. The curving has greatly increased. Shortly after this the right side became the seat of irregular pains; it began to "fall in." Three years ago the right hip began to pain her, and the thigh to bend. For the last three or four years she had found walking troublesome, the difficulty gradually increasing. The right tibia was considerably enlarged and markedly curved. The left leg was equally affected in the deformity. The ribs on the right side are considerably contracted.

At the Clinical Society (London), March 13, 1885, Mr. A. Q. Silcock presented specimens from a case occurring in a woman aged eighty two. The femora were curved

slightly and slightly thickened, and the tibia had an antero-posterior curve. The right tibia was specially thickened, and on section it was seen that the medulla was encroached upon. At the summit of the curve the compact bone had become more porous, but no new growth could be discovered. The periosteum of the thickened bone was not obviously affected. On raising the scalp the sutures were found to be obliterated, and the surface of the bone was smooth. The right parietal and frontal eminences were much exaggerated. The bones were greatly thickened. The thickness of the frontal bones was one inch and a quarter, of the squamous portion of the temporal bone one-third of an inch on the right and one-quarter of an inch on the left, of the occipital one-half an inch. The superciliary ridges were greatly exaggerated. The distinction between external and internal tables and diploë were almost obliterated except in one area; the bone was hard and compact, the dura mater was unduly adherent, and the inner surface of the cranium was rough; the bones entering into the base were not affected, but the roof of the orbit was thickened. The spine was doubly curved and twisted, but this curvature appeared to have occurred in early life, as section of the spine showed no recent changes. The viscera were all healthy. The brain weighed forty ounces, and was apparently quite normal. At this meeting Mr. Stephen Paget showed specimens from two of the cases described by Sir James Paget. Dr. Goodhart showed specimens from a woman at this same meeting.

The literature of our own country contains very little on this subject, so far as I can learn, and hence the value of the present case. The question of treatment came up for my decision, and it occurred to me that an osteotomy could be done to advantage. The patient, however, did not assent to this treatment.

Dr. Andrew H. Smith referred to a case, and inquired of Dr. Gibney whether it was not of the same nature as his second case. The patient was a woman, aged about fifty, who, while exerting the least amount of force in pulling to a stage door on Fifth Avenue, sustained a fracture of the right radius. Dr. Smith found that the bone had previously been enlarged and curved. The radius of the other arm was also enlarged and curved in its lower half. Both tibiæ were enlarged and curved, one very markedly. All these changes had taken place within three years. Replying to an interrogatory by Dr. Gibney, he said the patient had not suffered pains in the bones.

He inquired of Dr. Gibney whether if in his (Dr. Gibney's) case section were made to overcome the bow-leg, he would expect ready union?

Dr. Gibney replied that he knew of no reason why the changes which had taken place in the bone should interfere with union if they were operated upon. Being also asked what was the nature of the pathological process, he said it was a subacute ostitis, and that the deformity was due, not to predominance of the soft over the osseous substances in the bone, but to laxity of the ligaments. The bones did not seem to him to be bent.

A Case of Acromegaly.—Dr. C. L. Dana said he would like to have Dr. Gibney's opinion as to the relation between the disease in the case which he had last presented and that of acromegaly, of which he had a case under observation. In this disease there is an extraordinary hypertrophy of the bones of the extremities.

Ostitis Deformans in a Horse.—Dr. E. L. Partridge said Dr. Liautard once showed him a horse which he and his colleagues regarded as an unusual case. It was somewhat similar to that of the man presented by Dr. Gibney, for there was symmetrical increase in the size of the bones. The condition was spoken of by the veterinarians as big head. The animal retained his appetite, and seemed comfortable, but as the years passed the bones became very large, and caused the movements to become clumsy. The jaw especially was very large in this case.

Perforating Ulcer of the Duodenum.—Dr. George L. Peabody presented a case as follows:

The patient whose stomach and duodenum I show you this evening was admitted into one of my wards in Bellevue Hospital in November, 1889. He was an Irishman of good muscular development, thirty-eight years of age, unmarried, and a carpenter by occupation. He admitted that he drank in moderation.

Previously to this fatal illness he had always been well and strong; he had never had a severe illness of any kind, and, specifically, gave no history at all pointing toward a gastric or duodenal ulcer.

Six days before he entered the hospital he had been exposed to a heavy rain, and had got very wet. Following this prolonged exposure, and while still very wet, he worked for some hours in an open hallway, in a strong and cold current of air. During this exposure he perspired very freely in consequence of his hard muscular work. About eleven o'clock his work was finished, and he went home to bed. A chill soon followed, which was severe, but, as he thought, was not attended by fever. It was, however, soon followed by diarrhœa, which was severe at first, and continued with varying severity up to the time of his admission to the hospital. About forty-eight hours after the diarrhœa commenced he began to be nauseated, and soon to vomit. This vomiting continued, with irregular remissions, up to the time of his admission. During the continuance of the vomiting he coughed a good deal. With this cough there developed a well-marked pain, which he located at the level of the ensiform cartilage, and which he said extended thence laterally in both directions entirely across the front of the body.

Upon admission to the hospital he complained of this pain, which was moderately severe and accompanied by some tenderness on pressure in the same regions. He also complained of the cough, and he vomited a little at this time. After his admission he vomited only twice. He was very hungry, and begged to be allowed a more liberal diet than the milk to which I caused him to be restricted. The vomited matter was of dark brown, granular, watery material, of very offensive odor, and not very abundant. It ceased in response to ordinary treatment; and on neither occasion did it contain blood. His appearance at the time of his admission somewhat suggested the presence of peritonitis. His eyes were sunken, there was great facial emaciation, and a rather hard and moderately rapid pulse. His temperature, however, was not high (99.6° F.), and the pain and tenderness were not severe, and he was very hungry, as I have said.

Besides the ordinary anti-emetic treatment that seemed indicated, I ordered him only milk diet and cold applications to the region of the epigastrium. A few hours later he had several diarrhœal movements. These were dark in color and very watery, but they contained no blood. This symptom ceased without treatment during the night. The next day he expressed himself as feeling much better. He wanted to be allowed to get up and to eat solid food. He was, of course, kept in bed, and given only milk as food, in spite of his wishes. The pain and tenderness were still present, but not very severe; and the cough, vomiting, and diarrhœa had all subsided. After the cessation of these latter symptoms he had slept fairly well. He seemed refreshed and to need no additional treatment. He still had the facies of grave intra-peritoneal lesion, but he gave no other indication at this time of the nature of his malady beyond this, and the pain and tenderness.

During the second night after he came under observation he again had a sharp attack of diarrhœa, which ceased before morning under the use of an ordinary astringent mixture containing a small quantity of opium. On the following day his facial expression again impressed me as it had at first, and he still had some pain and tenderness, but neither nausea, nor vomiting, nor diarrhœa. His hunger was unabated. Up to this time his temperature had kept in the neighborhood of 100° F., but on this day—the third of his hospital stay—it rose to 103° in the

evening. His urine contained a small quantity of albumin, but was normal in other respects.

Suddenly, in the evening, he had several profuse, watery movements, and complained of intense and unendurable pain in the epigastrium and both hypochondriac regions. Morphine was given subcutaneously without controlling the pain. He passed rapidly into a condition of collapse, had a very feeble pulse, a cold surface, covered with profuse perspiration, and died at 9.15 P.M.

At the autopsy I found a large quantity of liquid intestinal contents in the upper part of the peritoneal cavity, with intense congestion of the peritoneum in the same situation. The stomach was moderately dilated, and its mucous membrane generally thickened, presenting, as is still well seen, the *état mamelonné* of the French pathologists.

In the posterior surface of the duodenum, three-quarters of an inch below the pyloric ring, was this circular ulcer, whose edges are smooth and whose diameter is rather more than half an inch. It had destroyed all the coats of the duodenum.

In view of the rarity of this lesion and the obscurity of its symptoms, it seemed to me that the case was worth recording in the proceedings of the Society.

Duodenal Ulcers Following Burns.—Dr. George F. Shrady said there were cases on record in the New York Hospital of duodenal ulcers following burns. He had seen one there when house surgeon.

Dr. Peabody remarked that it was true, duodenal ulcers did sometimes result from burns, but why the embolus should lodge in the duodenum seemed a mystery.

Dr. Polk inquired of Dr. Peabody what was the explanation of the ulcer in this case.

Dr. Peabody replied that he had no explanation to offer, yet he supposed its origin was similar to that of so-called peptic ulcers in the stomach. Unlike ulcer of the stomach, ulcer of the duodenum was said to be more common in men than in women. He had no explanation to offer for the cessation of the circulation of the blood at the seat of the ulcer in this case.

The Question of Operation.—Dr. W. T. Bull inquired whether there was anything in the course of the history which would suggest the propriety of abdominal section.

Dr. Peabody replied that the question of opening the abdomen was pretty thoroughly discussed, but there were no symptoms of peritonitis except in the facial expression, and no signs of perforation until an hour or two before death.

The President remarked that a number of cases had been reported with a similar history to that of Dr. Peabody's; cases in which the first evidence of trouble had either been intestinal hemorrhage so profuse as to cause death, or else perforation and fatal peritonitis. He believed that in the majority of cases of duodenal ulcers the diagnosis had not been made until after death. It was a curious fact, to which Dr. Peabody had already referred, that a very large percentage of the recorded cases had occurred in males, while gastric ulcer was markedly more frequent in females. In sixty-four cases of duodenal ulcer recorded by Krauss, ninety-six and two-thirds per cent. of the whole number had been males. The only case which he had himself seen confirmed by autopsy, was in a male; the ulcer was very large, and was situated one-half in the duodenum and the other half in the stomach. He had at present two other cases under observation, in which he believed duodenal ulcer existed, but the diagnosis remained to be confirmed. Bucquoy had published a series of cases, and given several differential points in the diagnosis. One was pain and distress in the right hypochondriac region, developing two or three hours after ingestion of food, gastric digestion often being performed without apparent disturbance. A second was a sudden and recurring intestinal hemorrhage in an apparently healthy person. An article had been published two or three years ago by Dr. William Johnston, of Washington, in which a very striking case of duodenal ulcer was described, in which these diagnostic points were prominent. In a recent paper Dr. Osler had expressed doubts of dependence being placed upon these differential points. With regard to the genesis of duodenal ulcer, its usual situation above the bile papilla pointed to a similar origin with gastric ulcer. Physiologically considered, this part of the duodenum might be regarded as a part of the stomach.

(To be continued.)

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 6 to April 12, 1890.

Taylor, Arthur W., Captain and Assistant Surgeon. By direction of the Secretary of War, leave of absence granted for six months, on surgeon's certificate of disability, with permission to leave the Division of the Pacific. Par. 10, S. O. 78, A. G. O., Washington, D. C., April 3, 1890.

O'Reilly, Robert M., Major and Surgeon. By direction of the Secretary of War, the leave of absence granted him in S. O. 24, October 16, 1889, amended by S. O. 252, October 29, 1889, both from this office, is extended one month. Par. 30, S. O. 81, A. G. O., April 7, 1890.

Wood, Marshall W., Captain and Assistant Surgeon. By direction of the Secretary of War, relieved from duty at Fort Randall, S. Dak., and to report in person to the commanding officer, Fort Meade, S. Dak., for duty at that post, reporting by letter to the commanding general, Department of Dakota. Par. 24, S. O. 82, Headquarters of the Army, A. G. O., Washington, D. C., April 8, 1890.

Jarvis, Nathan S., First Lieutenant and Assistant Surgeon. By direction of the Secretary of War, the leave of absence granted him in S. O. 34, March 20, 1890, Department of the Missouri, is extended fifteen days. Par. 22, S. O. 81, Headquarters of the Army. A. G. O., April 7, 1890.

Lauderdale, John V., Major and Surgeon. By direction of the Secretary of War, transferred from Fort Davis, Tex., to Fort Ontario, N. Y. Par. 2, S. O. 83, A. G. O., Washington, D. C., April 9, 1890.

Skinner, John O., Captain and Assistant Surgeon. By direction of the Secretary of War, transferred from Fort Ontario, N. Y., to Fort Davis, Tex. Par. 2, S. O. 83, A. G. O., Washington, D. C., April 9, 1890.

Perley, H. O., Captain and Assistant Surgeon. By direction of the Secretary of War, transferred from Fort Wayne, Mich., to Fort Mason, Cal. Par. 2, S. O. 83, A. G. O., Washington, D. C., April 9, 1890.

Burton, H. G., Captain and Assistant Surgeon. By direction of the Secretary of War, transferred from David's Island, N. Y., to Vancouver Barracks, Washington, D. C. Par. 2, S. O. 83, A. G. O., Washington, D. C., April 9, 1890.

Hopkins, William E., Captain and Assistant Surgeon. By direction of the Secretary of War, transferred from Fort Mason, Cal., to Fort Columbus, New York Harbor. Par. 2, S. O. 83, A. G. O., Washington, D. C., April 9. 1890.

Stephenson, William, Captain and Assistant Surgeon. By direction of the Secretary of War, transferred from Fort Verde, Ariz. Terr., to David's Island, N. Y. Par. 2, S. O. 83, A. G. O., Washington, D. C., April 9, 1890.

Willcox, Charles. First Lieutenant and Assistant Surgeon. By direction of the Secretary of War, transferred from Fort Columbus, New York Harbor, to Fort Bowie, Ariz. Terr. Par. 2, S. O. 83, A. G. O., Washington, D. C., April 9, 1890.

Official List of Changes in the Medical Corps of the United States Navy for the week ending April 12, 1890.

WHITE, S. S., Assistant Surgeon. Detached from the Minnesota and to wait orders.

HARRIS, H. N. T., Assistant Surgeon. Ordered to the Minnesota.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 12, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	9	5
Scarlet fever	85	7
Cerebro-spinal meningitis	7	5
Measles	273	14
Diphtheria	94	29
Small-pox	0	0
Varicella	6	0
Cholera	0	0

Caffeine has hitherto been believed to be a substitute for food, but, according to Professor Germain Sée, it furnishes only the primary tonic stimulation. A paper, recently read before the Academy of Medicine by Professor Sée, on the subject, winds up with the following conclusions: 1. Caffeine, in small and repeated doses (sixty centigrammes) per day, and which may be prescribed with advantage to soldiers on march, facilitates muscular work, in augmenting the activity not directly of the muscle itself, but of the motor nervous system, as much cerebral as medullary. The consequence of this double action is to diminish the sensation of effort and fatigue which constitutes a nervous phenomenon. 2. Caffeine prevents dyspnœa and palpitations following effort. 3. A man who gives himself up to prolonged violent exercise acquires the qualities of training. 4. In producing this excitation of the cerebro-spinal motor system, on which depends the augmentation of muscular tonicity, caffeine augments the waste of the carbon of the organism and particularly of the muscles, but it does not restrain the waste of the nitrogenous substances; it is, therefore, not in reality a means of retarding the wear and tear of the tissues (moyen d'épargne). 5. Caffeine, therefore, has not the property of replacing aliments; it only replaces the general tonic excitation which is produced by the ingestion of aliments. Thus it may be seen that the so-called "médicaments d'épargne," which were once so much vaunted, are daily losing credit. The legendary coca of Peru is also losing the beneficent properties attributed to it.

Death of Trélat.—One of the most distinguished members of the Faculty of Medicine of Paris, Dr. Ulysse Trélat, died on Friday last, the 28th inst., from the effects of pulmonary congestion, with which he was attacked about a week previously. He was sixty-two years of age. He was the second son of Ulysse Trélat, the celebrated alienist, and Minister of Public Works in 1848. He took his degree in 1854, then became agrégé in 1857, on which occasion he wrote his thesis on necrosis produced by phosphorus. In 1860 he was attached to the Central Bureau of Hospitals, then successively to the Maternity, the Hôpital Saint Antoine, to the Pitié, and finally to the Charity Hospital in 1872, to which he remained attached to the day of his death. He was appointed Professor of Clinical Surgery in the same year, elected Member of the Academy of Medicine in January, 1874, of which he eventually became President. He was also Commander of the Legion of Honor. His funeral, which took place in the Madeleine Church on Monday morning, was very largely attended. Military honors were rendered, the Faculty of Medicine and the Academy were officially represented by professors in their official robes. The other learned societies to which the deceased belonged were also represented. His interment took place in the Cemetery of Montmartre, when several orations were pronounced over his grave. The deceased having been President of the Academy of Medicine, the meeting of Tuesday last was suspended as a mark of respect to his memory.

Deaths from Chloroform.—Owing to an accident which lately took place at a hospital, in a patient while under the influence of chloroform during an operation, the director of the Assistance Publique has caused a report to be made of the surgical operations that have been performed in the Paris hospitals during the last ten years, and the conditions in which they were performed. It results from this work that the accidents due to the employment of chloroform have been in the proportion of 1 in 1,236, those due to ether have been only 1 in 12,581 cases.

An Album for Pasteur.—The Semaine Médicale reports that a committee, composed of British and American notabilities, has been formed to offer an album to M. Pasteur. The first page of this album bears, in French, under the signature of the Princess of Wales, the following inscription: "To the Great Monsieur Pasteur, the Benefactor of the human race."

Hypertrophy of Tonsils.—In order to determine the relations of hypertrophy of the tonsils in childhood to the general physical development of the children concerned, Dr. Upsenski examined the pupils of two military schools, between the ages of ten and fourteen, finding among them fifty-two cases in which hypertrophy existed. Of these, twenty were deficient as to height, weight, and circumference of the chest for their respective ages. A few were myopic; thirty-seven lacked acuteness of hearing; most of them were anæmic, with weak and hoarse voice. Breathing through the nose was difficult, and in most of the cases obstructed. With the tonsillar hypertrophy there was also granular or atrophic pharyngitis in almost every case, and in many there was swelling of the glands of the cervical and submaxillary region. In twelve cases the uvula was deviated to the right, in eight to the left; but this had no bearing on the hearing in these cases. In eighteen of the cases the father was dead, in seven the mother, the cause of death in most cases being some form of chest disease. The conclusion which was drawn from the study of these cases was, that between tonsillar hypertrophy and physical and psychical development there exist relations which rest for the most part, if not exclusively, upon inheritance.—*The Boston Medical and Surgical Journal.*

Diabetic Coma and its Treatment.—Stadelmann, as the results of clinical and experimental observation on this subject, comes to the following conclusions: 1. Diabetic coma—apart from accidental coma due to other causes—occurs only in the case of diabetic patients whose urine contains oxybutyric acid. 2. Almost equivalent in value with the recognition of oxybutyric acid is the determination of the amount of ammonia in the urine; while it is also far easier of performance. 3. Diabetic patients with an excretion of ammonia of more than 1.1 gramme per day, are in danger of becoming severe cases of the disease. 4 Patients excreting two, four, six, and more grammes of ammonia daily, need constant watching by the physician, and are in constant danger of passing into diabetic coma. 5. If the determination of the presence of oxybutyric acid, or the estimation of the amount of ammonia, cannot be carried out, at least the chloride of iron test should be made. If this gives a positive reaction, oxybutyric acid is present in the urine, and the cases answer to the statements made in the 3d and 4th conclusions. The converse of this is, however, not always true, for there are cases of diabetes with oxybutyric

acid in the urine, and even suffering from diabetic coma, whose urine does not give the chloride of iron reaction. 6. These severe cases in which there is an increase of the secretion of ammonia, or the presence of oxybutyric acid with the chloride of iron reaction in the urine, are only with the greatest caution, and with the simultaneous exhibition of alkalies, to be put upon a strict meat diet. 7. If there is fear of the development of diabetic coma, the patients should be put upon full doses of the alkalies, though, of course, with strict oversight and with proper interruptions in the treatment. 8. If coma has already developed, large intra-venous injections of a solution of the carbonate of sodium and the chloride of sodium should be given as quickly as possible; the patient being carefully watched meanwhile. The injections should be stopped if threatening symptoms appear, such as irregularity or marked retardation of the pulse, convulsions, or temporary cessation of respiration. After a time they should be recommenced, and the process continued until the urine becomes alkaline. 9. Subcutaneous injections of carbonate of sodium are not to be commended, on account of the pain and deep-seated inflammation they produce.—*The American Journal of the Medical Sciences*, March, 1890.

To Remove Superfluous Hair. — According to the *British and Colonial Druggist*, a good depilatory is made by mixing together in fine powder, 50 parts of barium sulphydrate, 25 parts of starch, 25 parts of oxide of zinc, and making into a paste with sufficient water. This is spread on the surface which is to be freed from hair, about an eighth of an inch thick, and allowed to dry. When this is effected (it generally takes about ten minutes) the mass is removed, leaving a perfectly hairless surface. Irritation does not occur, but the mixture should not be applied to the same place on two consecutive days.—*London Medical Recorder*.

National Legislation for the Prevention of the Spread of Contagious Diseases.—Congress has enacted the following law: An act to prevent the introduction of contagious diseases from one State to another, and for the punishment of certain offences. *Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled*, That whenever it shall be made to appear to the satisfaction of the President that cholera, yellow fever, small-pox, or plague exists in any State or Territory, or in the District of Columbia, and that there is danger of the spread of such disease into other States, Territories, or the District of Columbia, he is hereby authorized to cause the Secretary of the Treasury to promulgate such rules and regulations as in his judgment may be necessary to prevent the spread of such disease from one State or Territory into another, or from any State or Territory into the District of Columbia, or from the District of Columbia into any State or Territory, and to employ such inspectors and other persons as may be necessary to execute such regulations to prevent the spread of such disease. The said rules and regulations shall be prepared by the Supervising Surgeon-General of the Marine Hospital Service, under the direction of the Secretary of the Treasury. And any person who shall wilfully violate any rule or regulation so made and promulgated shall be deemed guilty of a misdemeanor, and upon conviction shall be punished by a fine of not more than five hundred dollars, or imprisonment for not more than two years, or both, in the discretion of the court.

Sec. 2. That any officer, or person acting as an officer, or agent of the United States at any quarantine station, or other person employed to aid in preventing the spread of such disease, who shall wilfully violate any of the quarantine laws of the United States, or any of the rules and regulations made and promulgated by the Secretary of the Treasury as provided for in Sec. 1 of this act, or any lawful order of his superior officer or officers, shall be deemed guilty of a misdemeanor, and upon conviction shall be punished by a fine of not more than three hundred dollars, or imprisonment for not more than one year, or both, in the discretion of the court.

Sec. 3. That when any common carrier or officer, agent, or employee of any common carrier shall wilfully violate any of the quarantine laws of the United States, or the rules and regulations made and promulgated as provided for in Sec. 1 of this act, such common carrier, officer, agent, or employee shall be deemed guilty of a misdemeanor, and shall, on conviction, be punished by a fine of not more than five hundred dollars, or imprisonment for not more than two years, or both, in the discretion of the court.

The bill was signed by the President, March 28th.

An Extraordinary and Tragical Case.—The following extraordinary and tragical case has recently been reported in the *Northwestern Medical Journal*. It shows how much it is necessary that physicians should be intelligent and well-trained men; and it is a most convincing argument that the State needs to guard itself against poor doctors as it would against a pestilence: A physician of forty years' practice attended a healthy young woman in her second confinement. After a comparatively easy labor she was delivered of a well-formed female child. In half an hour, as the placenta did not come away, the doctor proceeded to remove it. Gentle manipulation proving not sufficient he made use of such efforts that chloroform was necessary to deaden her extreme pain. Notwithstanding the fact that the patient suffered horribly, and was growing progressingly and alarmingly weaker, this man, for two hours, employed ever-increasing exertions to detach what he said was an adherent placenta. Finally he was prevailed on to send for assistance. The consulting physician made an examination, exclaimed "inversion," and after a hasty conversation between the two, the consultant asked for a knife to cut something off. What he removed he instantly made away with, and the patient a few minutes afterward died. Suspicions were aroused, however, and an investigation revealed the fact that the attending physician had actually enucleated with his hand the uterus, mistaking it for the placenta! The consultant, upon making his examination felt coils of intestine, and recognizing at once the awful condition of affairs, cut off the womb and took it away, hoping by this course to shield his friend.

Duration of Life in Norway.—According to a recent work on longevity, published in Norway, the average duration of life in that country is 48.33 years for men, and 51.3 for women.

Society of the Alumni of Charity Hospital.—At the meeting held April 8th, Dr. C. W. Stimson read a paper on the "Phonograph as an Acoumeter." The practicability of using the instrument was discussed by Drs. Noyes, Webster, Moore, Andrews, Mittendorf, Peck, and others. Dr. Webster thought there must be some bone conduction from insertion of the tubes into the auditory canal. This would of course be the source of a certain amount of error. Drs. Andrews and Peck urged the necessity of using the human voice as part of an acoumetric test. The system of graded bell sounds as introduced by Dr. Stimson was undoubtedly of value, but it is the human voice which deaf people want to hear. Dr. Rupp demonstrated a case of chronic œdema of the larynx.

Tenth International Medical Congress.—In a letter dated Berlin, Karlstrasse, 19, March 22d, Dr. Lassar, the Secretary-General of the Tenth International Congress, directs me to inform the Medical Profession of America, that a programme of the Congress and other communications will be distributed two months before the meeting among those who will have registered previously and received their tickets of membership. The latter can be obtained by sending application and five dollars to Dr. Bartels, Leipzigerstrasse, 75, Berlin, S. W. By so doing the members will save much crowding and time during the first days of the Congress.

THE FALLACY OF THE SO-CALLED HOT-AIR TREATMENT OF PHTHISIS.[1]

By W. GILMAN THOMPSON, M.D.,

PROFESSOR OF PHYSIOLOGY IN THE NEW YORK UNIVERSITY MEDICAL COLLEGE; VISITING PHYSICIAN TO THE NEW YORK AND PRESBYTERIAN HOSPITALS.

Among the many systems of treatment for pulmonary tuberculosis none have excited more wide spread interest than the so-called antiseptic methods, which are the immediate outgrowth of the discovery of the tubercle bacillus by Koch. One of these methods originated in Germany, about four years ago, and is employed to a considerable extent to-day in this country. It is based upon the fact that heat of a degree slightly above the body temperature destroys, or renders innocuous, the tubercle bacilli, so that if the germs can only be heated sufficiently *in situ* by the inhalation of super-heated air, they will cease their mischief. To accomplish this result several kinds of heaters have been devised. Krull, in Güstrow, De Renzi, in Naples, Weigert, in Berlin, Halter, in Halle, and Sears and Richardson, in Boston, have all invented new apparatus for hot-air inhalation.

This new treatment has been employed in a large number of cases of tuberculosis. Dr. Bowie, of London, reported last year, in *The Lancet*, that he had prescribed inhalations of air with the Weigert apparatus at 120° to 140° F. (48.8° to 60° C.), for a phthisical patient, with the effect of increasing the cough and expectoration for the first four weeks, although the general condition as to appetite, sleep, etc., improved, and the bacilli diminished. No medicine was given. Bowie omits the mention of the character of the diet or hygienic surroundings, and does not fully describe changes in the physical signs. He says that he has advised this treatment in several other cases, and has seen improvement in each.

Schmid recently reports several incipient cases of phthisis treated by Weigert's apparatus, in which the sputa lessened, and appetite and body weight increased.

Trudeau tried the Weigert method faithfully with four patients, who were under daily treatment by two sittings of two hours each, for periods varying from one to four months. He used air at 392° F. (200° C.) in the apparatus. Two patients became discouraged and gave up the treatment. Another, during a four months' course, seemed to have less dyspnœa and perspiration, fewer râles, with more nearly normal respiratory rhythm, and slight gain in weight. During the progress of these cases the sputum of the patients was injected into rabbits at regular intervals of five weeks, and its virulence as affecting these animals underwent no diminution whatever. In addition, cultures of the bacilli were made, and Trudeau arrived at the following conclusions: "1. The therapeutic value of hot-air inhalations in phthisis is doubtful. 2. The evidence obtained by the bacteriological study of the cases presented does not confirm the assumption that inhalations of heated air can either prevent the growth of the tubercle bacilli in the lungs of living individuals, or diminish the virulence of this microbe when it has gained access to them."

Louis Weigert reports, in the Medical Record, five cases treated by hot-air inhalations quickly raised to 320° F. (160° C.). These five patients were under treatment from one to six hours daily, for periods varying from one to five months, and they exhibited a certain amount of improvement in both physical signs and general symptoms.

The Weigert apparatus was exhibited by Dr. A. L. Stern before the Section in the Practice of Medicine of the New York Academy of Medicine, on February 19, 1889. This apparatus consisted of a double copper cylinder with a connecting tube, mouth-piece, and valves. The air within the cylinder is heated by a Bunsen burner or lamp to 482° F. (250° C.), though Weigert himself admits that the temperature when the air reaches the mouth-piece is "actually only about 320° F. (160° C.)." Dr. A. Jacobi, having had practical experience with this apparatus, at a subsequent meeting of the Academy, declared it to be very clumsy. It undoubtedly was both cumbersome and expensive.

A few days ago a cheap pamphlet was thrust beneath my door, entitled "Proofs that Consumption Can be Cured," and which advertises, with various eulogistic letters and newspaper notices, the merits of a cheaper and improved form of "Perfection Hot-air Machine," patented and for sale by the "Dr. Louis Weigert Co.," which is recommended for "consumption, asthma, chronic bronchitis," and a host of nasal and laryngeal affections!

Dr. Stern claimed for the hot-air treatment of phthisis that "complete cures" result, with "total cessation of cough" and expectoration, with disappearance of fever and night-sweats. He said, also, that after four months of treatment, the bacilli totally disappear. He also stated that, in Vienna, one hundred and fifty cases of phthisis had been treated by the new method, fifty of which had been reported.

In commenting upon the claims of Weigert and Stern, *The Journal of the American Medical Association* says that "all this reads like a fairy-tale," and continues, "there is but little doubt that this method of treating phthisis will be extensively tried."

Dr. A. Jacobi, at a meeting of the New York Academy of Medicine held on June 20, 1889, reported that he had been induced to give the Weigert apparatus fair trial at Bellevue Hospital, with the result of temporary improvement in the cases treated; but he was convinced that this improvement was due to rest and better air than the patients had had at home, rather than to any influence of the hot air. He expressed the opinion that little, if any, of the heated air ever reached the alveoli, and said that in the Weigert apparatus used the air fell from 300° F. (148° C.), in the cylinder, to nearly the temperature of the body by the time it reached the mouth. Two of his patients had severe cough and vomiting as a direct result of the inhalations.

Dr. E. L. Shurley, of Detroit, at a meeting of the American Medical Association, June 27, 1889, reported the use of the Weigert apparatus in twenty cases of phthisis. He considered only eight of these as having had a fair trial. Of these eight only two showed any kind of improvement, and the remaining six had to stop the treatment within one or two weeks, on account of sore mouths, dyspnœa, pains in the chest, nausea, or similar reasons.

Sears applied the hot-air treatment to four cases of phthisis. He employed an apparatus devised by G. L. Kingsley, of the Harvard Medical School, which must have been more efficient than others, judging from the results; for one patient became salivated, and the mouth grew so sore as to require intermission of the treatment. In an-

[1] Read before the New York Academy of Medicine, April 3, 1890.

other patient constant cough was excited. The third patient grew much worse, and died from hemorrhage several days after cessation of the treatment; and the second and fourth cases both had hæmoptysis for the first time in their history.

Professor Dr. Kohlschütter reported to a medical society in Halle-on-Saale the successful use of hot-air inhalations in several cases of pulmonary tuberculosis, and he spoke with much enthusiasm of the new treatment, claiming that by it a few more bacilli are destroyed each day, while the symptoms of cough, expectoration, etc., diminish.

The alteration in symptoms reported by those who have used the hot-air treatment, is no argument in its favor. None of these changes have been of a decided type, and everyone accustomed to deal with cases of tuberculosis in its various stages is familiar with the frequent slight changes in the cough, or sputum, or appetite, or body weight that naturally occur in the course of three or four months of the disease, and which are readily explained by variations in diet, hygiene, environment, etc. How often the faith that many such patients repose in any new treatment works a temporary improvement in their condition! The improvement was never very decided, in the best authenticated cases, and in many instances the patients were simultaneously taking creasote and other remedies. Moreover, the lung gymnastics, necessitated by deep inhalation, may, in certain cases, have been of benefit by expanding the lungs more fully, thus increasing tissue-change in various ways quite independently of any additional heat. The only observers (Sears and Trudeau) who have made a really thorough report of the relative number of bacilli present while the patients were under treatment, agree in failing to find any material diminution. The mouth would doubtless become much drier and more burned than it does, were it not for the fact that the salivary glands are stimulated to increased secretion by the irritation of the warm tube in the mouth.

The observers above cited all seem to have omitted to perform any simple experiments to determine whether the heated air really conveys its heat to the lungs or not, but contented themselves with speculation.

Dr. Sears says that, in other words, "a hot poultice has been applied to the lungs, and an active hyperæmia induced," and he alludes to the danger of the rarefied hot air favoring hemorrhage from vessels weakened by ulceration or aneurismal dilatation, while the patient himself is exposed to ordinary atmospheric pressure.

Halter, who first suggested the use of hot air inhalation for baking bacilli, has calculated that air heated to 122° F. (50° C.) is so rarefied and expanded as to equal in density air inhaled at an elevation of 1,350 metres, and air at 392° F. (200° C.) equals in density air at a height of 4,880 metres. Yet he disadvises forced inspiration of the hot air! In reviewing these statements, Lazarus very justly inquires how a patient is to draw such rarefied air into the lungs against the ordinary external atmospheric pressure, unless by extraordinary respiratory effort?

While the body remains under normal atmospheric pressure it is a physical impossibility to fill the lungs completely with rarefied air (*i.e.*, superheated air), or even to exert a negative pressure sufficient to forcibly rupture either normal or weakened vessels. A very simple calculation of the superficial area of the chest, multiplied by the normal atmospheric pressure bearing constantly upon that surface, shows the impossibility of exerting sufficient force by the chest-wall to sustain the external air, were the lungs filled with air sufficiently rarefied to rupture blood-vessels. The air would be condensed within the lungs to the normal pressure. Let anyone convince himself of this by closing the mouth and nostrils, and then trying to expand the air in the lungs by attempting to expand the chest.

Weigert and Kohlschütter not only claim that the hot air penetrates to the deepest alveoli, carrying great heat with it, but that the exhaled air has a temperature ranging as high as 140° F. (60° C.), and that this hot air destroys the bacilli in some instances, and lessens their virulence in others.

Krull claims that heated air acts like a cataplasm, dilates the lung capillaries, increases the rate of the circulation, promotes tissue metamorphosis, diminishes local symptoms, and increases strength. This claim is the more remarkable since he employs air heated but little above the body temperature. Krull also refers to the danger of inducing hemorrhage by the rarefied hot air. He now claims to get complete cures by inhalation of moist air at 112° F. (44° C.) for three-fourths or one and one-half hour twice daily. He says that there is no doubt about the hot air carrying its heat to the depths of the lungs, but omits to prove the assertion.

The duration of the sittings he reduces to fifteen or twenty minutes, once a day! (He reports five more successful cases in the *Berl. klin. Woch.*, 1889, p. 892.)

Dr. Lahnsen reports a case of tuberculosis cured by Krull's apparatus, and applauds it highly.

Wilson, in a paper read before the American Climatological Association in June, 1889, referring to Weigert's method, says: "Whether or not the tissues of the human lung can preserve their integrity when exposed to air of a temperature ranging from 212° F. (100° C.) to 480° F. (249° C.), sufficiently long to destroy the tubercle bacilli imbedded in them, remains to be demonstrated."

Halter, using inhalation of air at 392° F. (200 C.) to 446° F. (230° C.), claims that the temperature of the exhaled air is raised to 110° F. (43° C.), and he refers to the immunity from pulmonary tuberculosis of men employed with lime-baking ovens, which observation has led him to patent a mask for continuous inhalation of hot air. He uses both moist and dry air, and claims decided cures of diphtheria as well as tuberculosis.

With regard to the statement about the lime-bakers, the immunity does not appear to extend to stokers, who inhale equally hot air. The very high speed recently developed by the transatlantic steamers, has been attended by considerable loss of life among the stokers. Last October one of these men came under my care in the wards of the New York Hospital, suffering from a very acute pulmonary tuberculosis, developed while he was at work in the boiler-room of one of the ocean "greyhounds," and the surgeon of the same steamer stated that in his experience such cases were becoming more and more frequent among the stokers. Of course such cases, where the entire body is enveloped in the heated atmosphere, form a very different class from those treated by hot-air inhalation while the body is in an atmosphere of ordinary temperature. I therefore merely cite the above statements to oppose the argument of Halter, derived from the lime-bakers. I have, furthermore, the authority of an experienced naval surgeon for the statement that, in his experience in the service, he has never noticed or heard that the stokers were less liable to pulmonary diseases than other men, but, on the contrary, they are more liable to such complaints, not from the fact of their working in an atmosphere of very high temperature, but because, when greatly heated, they are so careless in exposing their bodies on deck.

The claims of Weigert and Kohlschütter, that the temperature of the exhaled air rises to 140° F. (60° C.) are not valid, because if a column of hot air be drawn in at the mouth or nose in ordinary respiration, the last inch or two of the column will be the first to be exhaled with the next expiration, and having been within the buccal or nasal cavity but a very brief time, it will not be as much cooled as the advance part of the column which has been drawn deeper in over a larger surface of moist bronchial mucous membrane. This first exhaled air will therefore raise the index of the thermometer and give rise to superficial and erroneous conclusions.

The only observers who thus far have attempted to ascertain whether hot air really *does* enter the lungs without

losing its heat, before keeping their patients sucking at a hot-air tube several hours daily for months at a time, are Mosso and Rondelli, of Turin. They separated two simple air-chambers by a moist membrane, and succeeded in cooling air from 392° F. (200 C.) to 76° F. (24° C.) by evaporation in its passage through the membrane from one chamber to the other.

They next allowed a dog to inhale hot air for fifteen minutes at 320° F. (160° C.), while thermometers inserted in the trachea and bronchi, respectively, showed practically no alteration in temperature. The rectal temperature also remained normal.

They used a hygrometer, and found, after inhalation of the hot air, that the exhaled air was as completely saturated as if the temperature of the inhaled air had been 66° F. (18° C.). They also estimated that the expanded hot air brings less oxygen into the lungs in a given time, and that the volume of exhaled air during respiration of hot air was not equal to that exhaled under normal conditions, by nine or ten per cent.—a circumstance which in itself is rather to be deprecated in phthisical subjects.

The results of the experiments of Mosso and Rondelli were entirely unknown to me until my own were completed, and I was pleased to find perfect accordance in our results. In addition, I made numerous other experiments which have not been previously performed, in so far as I am aware. I was interested to undertake these experiments because I could not believe, upon theoretical grounds, in the advantages claimed for inhalations of hot and of cold air, and I desired to convince myself and others by facts derived from experiments.

The theoretical objections to the method of hot-air inhalation appear to me as follows:

I. We are not accustomed to find any important changes in body temperature or in the character of the respiration in those who work in great heat, like founders, bakers, pottery glazers, stokers, and the like, nor in those who are exposed to arctic cold.

II. The widest variation of body temperature admitted by physiologists to occur in those who exchange an arctic for a tropical climate, does not exceed 0.5° to 1° F., and even this is not constant.

III. Very hot air in contact with the mucous membrane of the nose, mouth, pharynx, and larynx, will destroy their epithelium, and produce painful swelling and congestion.

IV. If it could reach further, it would cause destruction of the ciliated epithelium of the bronchi, and the delicate cells lining the air-sacs would be destroyed and desquamated.

V. It would cause dangerous capillary congestion in the lungs.

VI. The bacilli are many of them buried in large tubercular masses. It is not probable that if hot air could enter the bronchioles or air-sacs it could reach more of the bacilli than such as were by chance contained in the sputa. (Wiegert does not claim this himself.) To reach their real foci with sufficient heat to destroy them, the hot air must warm the surrounding blood.

VII. Blood-serum albumin is coagulated at various temperatures according to the reaction of its solution, and the relative amount of salts present. It may coagulate at as low a temperature as 122° F. (50° C.) (Charles), or as high as 163° F. (73° C.). The myosin in the muscles of the trachea and bronchi passes into heat rigor (coagulates) at 131°–140° F. (55°–60° C.) (Charles). The protoplasm of the various cells and blood-corpuscles would all be hopelessly injured by the heat.

VIII. The blood itself, unless the pulmonary vessels were greatly congested and the heart action greatly enfeebled, would tend to carry off the heat of the air very rapidly. An enormous surface of blood is exposed in the lungs, which is being constantly replaced with each cardiac pulsation by fresh quantities of blood unheated by the air, and ready to absorb more heat-units before they can accumulate sufficiently to damage either bacilli or protoplasm.

IX. The natural process of vaporization of the water from the mucous surface is amply sufficient to absorb all the heat-units that can be brought to the bronchi by the superheated air.

X. Only about one-tenth of the air in the lungs is exchanged with each respiration. Suppose, for a moment, that an instantaneous mixture of the air of one inspiration with the residual air of the lungs could occur—which is impossible for several reasons—then one volume of air at, say, 200° F.—nine volumes of air at 100° F.—would reduce the temperature of the mixture to 110° F., and this air would be cooled by evaporation of water long before another inspiration of hot air could raise the temperature still more.

In the face of all these well-known considerations it is difficult to believe that anyone could for a moment expect to fill the lungs during life with air hot enough or cold enough to kill bacilli. Koch says that bacilli grow best at 99° to 101° F. (37° to 38° C.), and cease to multiply at 108° F. (42° C.). Recent researches show that to certainly kill these germs a still higher temperature appears to be necessary.

EXPERIMENTS.—My own experiments were directed to determine:

1. How far can hot and cold air, respectively, be made to convey heat or cold into the air-passages.

2. The influence of evaporation upon heat-loss.

3. The influence of conduction and radiation upon heat-loss.

4. Any changes in body temperature, either local or systemic, produced by the inhalations described.

In the following experiments a very simple apparatus was used for heating the air. It consists of an iron pipe eleven feet long, bent into a close coil three inches in diameter, beneath which are placed several powerful Bunsen burners. Air is forced through one end of the coil in a continuous current from a large treadle reservoir-bellows. In traversing the coil the air is heated to 500° F., (260° C.). From the opposite end of the coil the iron pipe is bent out straight for eight inches, and connected with an inhaler made to fit tightly over the head of the animal. The inhaler has a valve which prevents the exhaled air from entering the coil, and this air passes out through a lateral opening in the inhaler. One thermometer is placed in the inhaler close to the animal's nose, and another is placed six inches distant in the tube leading from the coil. In this way the maximum temperature of the air from the coil is recorded, as well as the temperature of the air actually inhaled at the nostrils. The principle is in every way identical with that of the apparatus employed for tubercular cases, but instead of the animal sucking the hot air through the heater for himself, it is forced through in a rapid continuous stream by a bellows. In this manner the inhaler and tubes are all kept much hotter, and the temperature at the nose is easily maintained at a continuously high rate. All the thermometers used for the apparatus or animals, were of course carefully tested and compared with each other.

The animals were anæsthetized, and thermometers were placed in the lungs or trachea, or both, through small openings which they fitted so closely as to make the holes air-tight. In answer to the possible objection that, when the pleura is opened to admit a thermometer, the lung might collapse and not admit the hot air, I refer to recent experiments upon the opened pleural cavity, made by Drs. O'Dwyer, Phelps, Northrup, and myself, published in the "Researches of the Loomis Laboratory, for 1890," which demonstrate that the lung does expand again, as soon as the opening is properly closed, in expiration. As an additional proof, in many cases I inserted a thermometer between the lobes in *each* lung, and so soon as the small openings in the pleuræ were closed, respiration went on normally, and so continued. Hence a thermometer carefully placed between two adjacent pulmonary lobes, or in the lung tissue itself, does not practically interfere in the slightest with the expansion of the lung, and the entrance of air in the normal manner.

Experiment I.—Small dog. Temperature before inhalation: Rectum, 102.5° F. (39° C.); lung, 102.5° F. Air, 120° F. (49° C.) at nose, was inhaled for five minutes. No alteration in temperature of lung or rectum.

Experiment II.—Dog. Temperature before inhalation: Rectum, 100° F. (37.7° C.); lung, 100.2° F. Hot-air inhalation was started at 150° F. (65° C.), rapidly increased to 200° F., and finally to 220° F. (105° C.). This was the temperature one inch from the nose. The temperature near the coil was 200° F. higher. Inhalation was maintained for one and a half hour. During this time the temperature in the lung fell 1.2° F., and in the rectum 2° F., while the respiration fell from 26 to 14. The animal took the chloroform very ill, and a great deal was administered, so that a slight chill ensued, with the fall of temperature observed in the lung and rectum. Clearly there was no entrance of hot air to the lung in this case. The animal was subsequently allowed up, and it appeared bright and well.

Experiment III.—Small dog. Temperature of lung before inhalation, 104° F. Inhaled air at 350° F. (177° C.) at nose for fifteen minutes, at the end of which time the temperature of the lung had risen only 1.5° F. On being allowed to get up the dog showed panting respiration, and a very red tongue with congested lips. It should be remembered that the heat of the blood which is ordinarily lost in warming the inspired air, when that air is below the blood temperature, is no longer so lost when the inspired air is very hot. This may account for the rise of a degree or two in the temperature of the blood, which is due to accumulated heat rather than to heat brought in by the air. It is estimated that 2.6 parts per 100 of the heat produced by the body is normally lost in warming the inspired air (McKendrick), chiefly in the nose and trachea.

Experiment IV.—Bitch, with thermometer placed in right lung. Before inhalation, temperature in vagina 102.2° F. (39° C.); in right lung, 103.6° F. (39.6° C.). The inhaler was worn one and a half hour, and the air was started at 180° F. (82° C.), and rapidly increased to 290° F. This was the temperature close to the nose and mouth, corresponding to the position in which the writers above quoted claim to have taken the temperature of "expired air"—except that my valve and thermometer were a little nearer the mouth. During the first hour of inhalation of air at considerably above 200° F. (93° C.), the vaginal and lung temperatures were frequently noted, and they remained absolutely unchanged from the record prior to the inhalation. Surely, if air at 200° F. (93° C.) were to raise the temperature of the lungs at all, it would do so within an hour's time. During the next half-hour, as the temperature of the inhaled air was raised to 290° F. (143° C.) at the nose, the animal became very uncomfortable and restless, and there were evident signs of local irritation from the heat, such as profuse salivation, red and swollen tongue and lips, and congested conjunctivæ. Under these conditions a rise of body temperature occurred amounting to 1.8° F. (1° C.), so that the vaginal temperature at the end of one and a half hour registered 104° F., and the lung 105.2° F. (40.5° C.). This rise of 1.8° F. or more in the body temperature often occurs when a dog is restrained in an irksome position for some time, and subjected to almost any kind of operation. I have frequently seen the temperature of animals rise 2° F. while they were struggling to resist an anæsthetic. It does not seem to me fair to refer the slight rise in the final half-hour of this experiment to any effect of the heat, other than the local discomfort and irritation produced near the inhaler.

Experiment V.—Large bitch. Thermometer in trachea close to larynx, before inhalation, 102.2° F. (39° C.); vaginal temperature, 105° F. (40.5° C.). Air six inches from nose started at 240° F. (115° C.), and rapidly heated to 440° F. (227° C.). At the nose the temperature was 200° to 315° F. (157° C.). Inhalation maintained one and a quarter hour, during which time the temperature in the trachea rose only 4° F., *i.e.*, to 106.2° F. (41.2° C.). The tracheal temperature showed interesting fluctuations of 0.4° F. between deep inspiration and expiration (measured by a thermometer without the usual detached index). Air which is cooled over 200° F. in entering the trachea, traversing a distance of only six or eight inches from the nose, is not likely to convey much heat through a greater distance beyond, into the alveoli!

Experiment VI.—Large cat. Temperature before inhalation: In lung, 100.4° F.; in rectum, 99° F. Respiration, 40. Inhalation was begun at 200° F. at cat's nose, and rapidly raised to 300° F. (149° C.) at the nose, and continued for one hour. Six inches nearer the apparatus the thermometer recorded 425° F. (218° C.). For fifteen minutes there was no rise in the temperature of the lung or rectum. The cat then began to exhibit great local irritation about the face; the eyes were suffused, the lips and tongue very red and swollen, and the respiration in half an hour became very shallow, and ran up to over 200. At the end of an hour's inhalation of hot air between 260° and 300° F. (149° C.) at the nose, the lung and rectal temperature both rose 6.8° F. The inhalation was then suspended, the cat being very feeble, and in one hour more respiration and temperature were normal and the cat walked naturally about.

Experiment VII.—Dog. Temperature before inhalation: Lung, 102.6° F.; rectum, 102.2° F. (39° C.). Inhalation started at 200° F. (93° C.) at nose, and was rapidly increased to 280° F. (138° C.) and so continued. In ten minutes there was no rise of temperature. At the end of three-quarters of an hour the lung and rectal temperatures had both slowly risen 2.4° F., and during the remaining fifteen minutes of inhalation there was no further rise. The animal exhibited great irritation about the nose and mouth.

Experiment VIII.—Large cat. Inhaled air from 250° F. to 270° F. (132° C.) at the nose (500° F. in the tube of the apparatus). Inhalation maintained for twenty minutes, during which time the temperature of the lung rose from 100° F. to 102° F., and the temperature of the rectum from 101° F. to 103° F. Respiration became panting, and very shallow and rapid, finally reaching 250 per minute. The tongue and lips became intensely red and swollen; there were salivation and thirst, with every indication of great discomfort about the head, which was completely enclosed in the inhaler. I have frequently seen a similar rise of temperature in cats, irritated in other ways, under anæsthesia. A temperature of 270° F. (132° C.) at the mouth and nose is hot enough to irritate any animal into panting respiration, with great disturbance of the circulation and heat-regulating mechanism. The 2° F. of elevation of the lung temperature in this case is a very trifling one, were it really due to the heat of air inhaled at 270° F. (132° C.), and because a similar slight rise may be produced in other ways, merely from irritation of various kinds. I cannot believe that in this instance the heat of the air was conveyed to the alveoli direct.

Experiment IX.—Dog. Two thermometers placed in the trachea, one at the larynx, the other two inches below. These thermometers varied from 103° to 103.4° F. (39.5° C.), fluctuating 0.4° F. with each respiration before the inhalation. Hot air was then inhaled through the nose, where the temperature was 240° F. at the start, rapidly elevated to 300° F. (149° C.), with only 1.2° F. rise in the tracheal temperature. The animal then died from heart-failure under chloroform. Tracheotomy was at once performed, and the hot air tube was inserted at the first ring of the trachea. The second thermometer, two inches below, was left in the trachea. Through the tracheotomy tube artificial respiration at 300° F. (149° C.) was maintained for ten minutes. The chest was opened, a small hole was cut in the lung, and a long-stem thermometer was placed directly in the lung substance. The chest was closed, and the thermometer index was read from the outside. During the ten minutes of forced

respiration the temperature of the lung rose from 103.2° F. to 106° F. (41° C.), less than 3° F.! The lungs were then excised, with the thermometers and tracheotomy tube *in situ*, and artificial respiration was continued outside of the body for twenty minutes more. The temperature of the air on entering the trachea was between 320° F. and 355° F. (180° C.). The tracheal temperature two inches below could not be made to rise above 140° F. (60° C.), and the temperature of the lung tissue gradually fell to 103° F.

These experiments show: I. That when air at a temperature of 300° F. + is forcibly driven into the lungs of a recently killed dog, the moisture of the lungs, notwithstanding the stoppage of the normal circulation, is still sufficient to cool the inhaled air to nearly the temperature of the body. II. The cooled air of exhalation prevents the temperature in the trachea from rising above 140° F., although the hot air of inhalation exceeds 300° F. During a part of the experiment, I endeavored to fill the lungs much more rapidly and fully than in normal breathing; but even these efforts failed to raise the lung temperature beyond 2.8° F. above the normal.

In view of the statement that a temperature above 102° F. retards the growth of tubercle bacilli, it is of interest to note that the normal temperature of rabbits is 102.5° to 103° F.; that of guinea-pigs, 103° F.; of monkeys, 102° to 102.5° F.; of pigeons and fowls, 108.5° to 110.5° F.; whereas it is well known that all of these animals are readily affected by pulmonary and other forms of tuberculosis.

Experiment X.—The laws of the relations of temperature to evaporation of fluids are too familiar for repetition here, but the following simple experiment is a striking illustration of the rapidity with which the heat of the air may be radiated from a non-isolated conducting tube, and of the rapidity with which it becomes latent in vaporizing water.

Through one end of a piece of rubber-tubing, 3½ feet long, of ⅝ inch bore, and 1½ inch thickness, a strong continuous current of air was forced as rapidly as a large reservoir-bellows could be operated. The temperature of the air at the tube entrance was recorded, at a distance of fourteen inches it was again recorded, and at the exit, three and one-half feet distant, a third thermometer was placed. The air was forced through for some minutes, when the temperature read as follows: Entrance, 260° F.; 14 inches from entrance, 205° F.; 3½ feet from entrance, 130° F. The tube was then moistened on the inner surface by pouring water through it. All the water was removed, except the little which wet the inner wall of the tube. Hot air was again forced through for some minutes at 280° F. (138° C.), when the exit thermometer recorded only 90° F. (32° C.). Therefore, merely moistening the tube caused a fall of 40° F. in the exit temperature.

Experiment XI., showing the effect upon the hot air of vaporization of water.—Large mongrel bitch, weighing eighty pounds. Normal temperature: Rectum, 103.5° F.; vagina, 103.5° F. The abdomen was opened, and the large intestine was cut in two. A half-inch glass tube was inserted in the distal end, and a stream of water was forced through the instestine toward the anus, to wash out the rectum. The intestine being clean and empty, a large glass nozzle was fitted air-tight into the rectum, and through it a stream of hot air was blown, which traversed the large intestine and passed out at the abdominal opening, where a thermometer recorded the exit temperature. The temperature of the injected air at the rectum was started at 200° F.; in eight minutes it rose to 300° F., at the end of half an hour to 340° F., while the entrance temperature rose from 200° F. to 300° F.; the exit temperature rose from 90° F. to 98° F. only. Later, as the air-current was greatly quickened and the intestine became a little drier, the exit temperature rose to 120° F., but I was unable to get it above this limit, though the hot air-current was continued twenty minutes longer (fifty minutes in all). To estimate roughly the relative quantity of moisture in the dry, hot entrance air and the same air after traversing the moist mucous surface of the intestine, I used a hygrometer. The instrument was not accurate, as the scale was somewhat arbitrary, but it served to show the relative moisture. Upon this hygrometer scale of 100° the air of the room stood at forty-seven per cent. My own deeply exhaled air indicated seventy-eight per cent., the hot, dry air at the dog's rectum ten per cent., and on emerging from the intestine above, sixty-two per cent. During the entire experiment the mouth temperature remained unaltered at 102° F. The abdominal incision was then closed, and the animal, after recovering from the chloroform, ran actively about the laboratory. An hour later she was killed. The injected hot air had been so thoroughly cooled, that I expected to see that several feet of intestine had been traversed, but great was my surprise to find that the distance from the intestinal incision to the rectum was only five inches. In other words, the moisture of five inches of intestinal wall by evaporation cooled the air from 340° F. down to 130° F., and maintained this reduction through fifty minutes, although the air-current was as rapid as a large bellows could make it. Curiously enough, the dog, constantly anæsthetized, was far more distressed during the experiment than were any of the other dogs after inhaling hot air for even longer periods. At one time the respirations rose to 98 and were very labored, and I was obliged to discontinue the injection to allow the animal to recover, which she did very promptly.

Cold Air in Hæmoptysis, Pneumonia, and Tuberculosis.—Dr. P. de Tullio, of Naples, has recently suggested the employment of cold-air inhalations for control of pulmonary hemorrhage. He forced air through a coil of tubing surrounded by ice and salt, and cooled the air to 0° C. He claims to have checked hæmoptysis in three severe cases, after failure with other means, such as drugs, ice to the chest, etc. In the *Meaical Recorder* for 1889, Dr. G. Lipari, of Palermo, in discussing the etiology of pneumonia, thus explains the influence of cold air in occasioning that disease. He says that cold atmospheric air, when inhaled, paralyzes the ciliated epithelium of the bronchi, and causes their mucous membrane to swell, and this favors the descent of the pneumococci into the alveoli.

So much for theory. The facts concerning the supposed inhalation of cold air are no less striking than those above cited in regard to inhalation of hot air. I took the same coil used for the hot-air experiments and imbedded it in a mixture of snow and salt; the bellows was operated outside of the window, in an atmosphere of 27° F. In this way the air after passing through the coil registered less than 40° F. at the animal's nose.

Koch says that a temperature of 85° F. (29° C.) must be produced before tubercular bacilli are checked in their growth.

Experiment XII.—Large dog, chloroformed. Temperature before inhalation: In trachea, 99.5° F.; in lung, 99.6° F.; in vagina, 101° F. Inhalation continued one and a quarter hour. Temperature in coil, 30° to 27° F. Temperature at nose, at commencement, 65° F., rapidly reduced (as inhaler was cooled by air from coil) to 40°, and finally to 37° F.

Temperature in the trachea fluctuated 4° with each respiration. During crying, under partial anæsthesia, it would fall with very deep inspiration 1° to 2° below the average record in the trachea at the time. The tracheal temperature gradually fell, and at the end of one and a quarter hour, the total fall was 10.4° F., whereas after three-quarters of an hour interval, the temperature of the lung remained unaltered, and in the remaining half-hour, when the room and the animal's body grew cold, it fell only 2° F., and the vaginal temperature fell 3° F.

The animal recovered promptly his condition when allowed to get up, and seemed uncommonly lively. A fall of only 2° F. in the temperature of the lung, after one and a quarter hour of inhalation of air below 40° F., will never

be sufficient to control pulmonary hemorrhage through vaso-motor stimulation. No one would think of controlling capillary oozing on the surface of the body by reducing the local temperature only 2° F.! Even should the hemorrhage come from the vessels of the upper trachea, the fall of only 10° F. there would not control it. It often requires prolonged direct application of ice to produce sufficient vaso-motor stimulus to control hemorrhage, and even that has frequently failed in post-partum hemorrhage.

Experiment XIII.—Cat, chloroformed. Temperature before inhalation: Lung, 99° F.; rectum, 99° F. Inhalation of air at 40° F. (at nose) was continued for one hour, when the temperature of the trachea was found to have fallen 5.2° F. The temperature of the lung fell only 3° F., and that of the rectum 4° F. I have often seen the temperature of a cat fall considerably more during operation under prolonged anæsthesia. There was 1° F. of fluctuation between inspiration (fall) and expiration (rise) in the trachea.

It is very difficult to conduct air from any cooling apparatus to the mouth without its gaining a few degrees in temperature if the room is warm. I have found it so even when external air was used at 27° F. and forced through an iron coil eleven feet long, imbedded in snow and salt. It would be doubly so in summer, when the warm atmospheric air must first be cooled in the coil. It is possible to cool air in this manner to nearly the freezing point, but it would be hardly practicable to do so for cases of sudden pulmonary hemorrhage. Moreover, the cool air, as it enters the mouth or nose, meets a surface constantly warmed by the air of exhalation, and by the local blood-stream. If, every time that we stepped from a furnace-heated room on a winter morning, into an atmosphere below the freezing-point, the temperature of our lungs fell 10°, or even 2°, we should have to be constructed on the principle of batrachians to survive it.

In a discussion before this Academy on November 26, 1889, Drs. Beverley Robinson and J. M. W. Kitchen called attention to the clinical fact that patients who have been using warm inhalations are particularly liable to contract colds on going too suddenly into a cooler atmosphere. This is doubtless true, but I think that it must be attributed to the influence of subsequent atmospheric changes upon the upper air-passages, and not to any effect upon the bronchi or lungs.

In performing all the experiments reported, I have received very valuable assistance from Dr. T. D. Coleman, and from Messrs. W. Coleman, Coudert, and Holden, students at the University Medical College.

Conclusions.—The following conditions combine to secure a uniform mean temperature of the air in the lungs, and prevent the entrance of superheated air, as such.

The great vascularity of the pulmonary tissue; the extensive surface of the air-sacs and blood-vessels; the slow diffusion of the tidal with the residual air; the uniform temperature of the blood; the remarkable heat-regulating mechanism of the entire body, which constantly tends to prevent local increase of temperature through the agency of a very rapid blood-stream; the low specific heat of water, and of the blood, which is so largely composed of water; the large quantity of blood in constant circulation, approximately fourteen pounds in man; the enormous number of heat-units rendered latent by vaporization of water, and the ease with which water can pass from the blood-plasma to the surface of mucous membranes, in considerable quantity; the conduction of heat by the body tissues.

Conclusions derived from the preceding experiments upon cats and dogs:

1. Continuous inhalation of air heated from 200° to over 300° F. at the nose does not raise the temperature of the lungs at all in some cases, even when inhaled for an hour or more.

2. In other cases, if continued for an hour and more, there may be a slight rise of from 2° to 4° F., due to various causes other than the entrance of hot air into the alveoli.

3. The temperature of the trachea under corresponding conditions rises only 4° to 7°. Cold air does not affect the temperature of the trachea or lungs any more than hot air, and is therefore equally useless as an inhalation for any clinical purposes whatever.

I have received, too late for review in this article, a very valuable paper upon the theoretical objections to the use of the hot-air inhalation treatment. It is by Dr. W. L. Cary, physician to the Brooklyn Throat Hospital, and it is altogether the most able and scientific refutation of the hot-air inhalation theory, based upon purely theoretical grounds, which has yet appeared.

There are doubtless many physiological experiments in regard to which one must not reason too closely from the lower animals to man, but it seems to me that the fundamental conclusions derived from the experiments herein reported, are of a type which must necessarily apply to man as truly as to the lower animals, because they are based upon sound laws of physics, and they afford one more illustration of the great value of vivisections, conducted with the object of preventing the employment of methods powerless for the relief of human diseases, the ignorant use of which can only bring great discomfort to the patient.

The Question of Contagion in Influenza.—Dr. A. A. Armstrong, of Fair Haven, N. J., writes: "The following fact offers strong evidence against the contagiousness of la grippe. It is that during the epidemic I treated over two hundred cases without getting the disease, but am now recovering from a severe attack contracted when I had no cases at all." On the other side is the following from *The Sanitary Inspector:* Dr. Trudeau, who has charge of the Adirondack Cottage Sanitarium for consumptives, fearing that an attack of the prevalent influenza might prove disastrous to many of the invalids, quarantined the place against the disease as soon as it appeared in the neighborhood. And, writing January 30th, he says that while the disease has attacked a great majority of the people living in the surrounding country, and dwellers and visitors at the villages and boarding-houses, there has not been a single case in the sanitarium.

THE HOT SPRINGS OF ARKANSAS AND THE TREATMENT OF SYPHILIS.[1]

By R. W. TAYLOR, M.D.,

PROFESSOR OF DERMATOLOGY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL; SURGEON TO CHARITY HOSPITAL, NEW YORK.

In compliance with the earnest wish of the enterprising Secretary of this Society that I should contribute to its proceedings, I have decided to direct your attention this evening to the question of the value of the Hot Springs of Arkansas in the treatment of syphilis.

From time out of mind the waters of mineral springs have been regarded by the laity as curative and even specific in the treatment of skin diseases especially, and in certain visceral and arthritic diseases. There has been, and perhaps always will be, a deep-rooted belief that waters made in the laboratory of nature possess an occult and potent effect far in advance of any production of the chemistry of man. Among the many and varied mineral and thermal springs of this country those of the Hot Springs of Arkansas have undoubtedly taken the most prominent rank, and among the laity, and even among the profession, there is a widespread belief in their efficacy in syphilitic affections, skin diseases, and those of a rheumatic nature. For many years I have had exceptional opportunities for studying the effects of the waters of the Hot Springs and the treatment pursued there upon patients who have been under my care and were temporarily sent there for benefit; upon patients who had been under other physicians prior to their sojourn there, and upon cases whose treatment had been begun there. From this large number of cases I hope to be able to present a fair estimate of the value of these springs as a therapeutic resource in the treatment of syphilis. Having done this, I propose to review in a general way the methods pursued among us in the treatment of syphilis, and to see how far the faultiness and derelictions in these methods are responsible for the fame or notoriety of these thermal springs.

An analysis of the water of the most prominent springs in the Arkansas Valley shows that their chief ingredient is silicic acid, and that it, with iron, alumina, lime, magnesia, potash, soda, with traces of iodides and bromides, exists in the proportion of eight and one-half grains to the gallon of water. It is very evident that no startling effect can be produced by this natural solution, yet some of the advocates of the springs speak in quite positive terms of the specificity of the waters, whatever that may mean. Others claim that their benefit resides in the electricity produced by chemical decomposition, with which they are said to be charged; while others think that they are imbued with a peculiar heat which is curative. To my mind the salutary and hygienic effects of these waters (as far as they are productive of good) resides in their heat alone. The stimulation of the capillaries and of the circulation generally, including the lymphatic system, as well as the stimulation of each individual cell of the skin, by the heated water, and the brisk frictions subsequent to the bath, in my judgment act as profound vitalizing agents and are productive of great benefit. But there are many accessory conditions which appertain to a sojourn at these thermal springs which play a very important part in the hygienic reconstruction which is often gained. Having taken the long journey, frequently, and after much anticipation, preparation, and often at great sacrifice in the matter of time and money, patients arrive at the springs with an earnestness of purpose and with a fixed idea that they will make any personal sacrifice, particularly in the matter of creature comforts, in order to be benefited or cured. They for a time undergo personal reformation, and usually sedulously refrain from alcoholics, from tobacco, from the card-table, with its late hours, and from sexual indulgence. They, as far as they can, leave behind them all business and social cares; they eat regularly; go to bed early, and perhaps sleep late, and, in short, conform as far as possible with the most rigid hygienic rules. Then, again, they have an entire change of scenery and of domestic relations, and, in fact, of the whole routine of life. They breathe a pure air; have plenty of opportunity for outdoor exercise, and generally enjoy rest and contentment. Certainly no one can ask for more auspicious auxiliaries to medical treatment.

It has been claimed that the sedation and tendency to sleep induced by the baths at the Hot Springs are peculiar and due to some occult effect of the waters. It is true that, as a rule, hot baths usually have an opposite effect, but I have many times seen the same soporific result follow hot salt-water baths taken at our seaside resorts. Then, again, in many instances, I have found that excitement and sleeplessness followed baths taken at the Hot Springs.

Let us now consider the conditions in which benefit may accrue to syphilitics who undergo treatment at the springs. While I am disposed to give this celebrated resort its full meed of praise in the treatment of syphilis, I must here state my emphatic belief that, in the majority of cases, there is not the slightest necessity of going so far away to attain a cure, and that a very large number of the cases which go there do so because they have not been properly handled at their homes. In other words, the faultiness in the physician's methods of treatment and his shortcomings in the management of his patients are, in many instances, the real reasons why patients have to betake themselves so far away for relief. This portion of my subject will be fully considered later on. Then, again, in very many instances the apathy of the patient; his carelessness and irregularity in following treatment; his absorption in business matters; his often flagrant want of attention to health and hygiene, so impair his physician's efforts that he perhaps obtains no good, and possibly grows steadily worse.

At no time during the primary stage of syphilis does treatment at the Hot Springs offer any advantage whatever. Treated on the classical lines, the chancre can always be healed, and in the rare event of phagedæna we are certainly at home as well equipped as our colleagues at the springs. In like manner no peculiar benefit can be derived in the early exanthematic stage. At this time the general health and nutrition of patients is usually good, and they, as a rule, respond readily to the action of mercurials. Indeed, under proper treatment in the vast majority of cases in this, the crucial period of the disease, they may be so benefited that the backbone of their ailment may be broken. I allude to the early part of the secondary stage of syphilis as being the crucial one in their history, because I firmly believe that if patients are then treated actively, suitably, and with due conservatism, a future immunity to the disease may be gained, that is, that they may be cured.

I believe that the rebelliousness and malignancy of syphilis which are seen in many cases during the secondary and the tertiary periods, are due to the fact that at the onset of the disease the treatment has been too much attenuated, that it has been prosecuted with apathy, or that it has not been adopted at all. Early in the disease the newly formed infecting granulation cells are proliferated in great abundance, they possess a great tendency to multiplication, and to permeate the tissues generally. Lodged in the tissues they induce irritative and inflammatory processes which modify their structure, and perhaps interfere with or destroy the functions of organs and parts. In this way dermal, cerebral, spinal, ocular, and visceral troubles are induced.

To my mind no duty can be more clear and imperative than that which should prompt us to use actively and boldly, but with cautiousness and circumspection, the remedies which will destroy these young infecting cells, which we know have this great power of multiplication early in syphilis. These cells are more easily disintegrated and absorbed when they are young than when they are

[1] Read before the Clinical Society of the New York Post-Graduate Medical School, January 11, 1890.

older, and if they are permitted to remain they almost inevitably increase in vast numbers, become scattered throughout the system, and then act as foci for the perpetuation of the disease, and starting-points, after periods of quiescence, of later reinfection.

There is a stock phrase used by many that mercury and time will wear out syphilis. It conveys a vicious teaching and leads us into a free-and-easy, happy-go-lucky, procrastinating way of treating this serious disorder.

In treating syphilis we should put in our most effective work when the disease is most amenable to our blows, and not dally with it and allow it to gain firm hold on the system. Therefore, I say that if an energetic and systematic treatment of syphilis is begun early and followed up, few cases will feel the necessity of going to thermal springs for relief. But, as I have already said, some cases will not be well treated, and others will not avail themselves of good treatment, therefore it is probable that in all time these syphilitic pilgrims will journey to their Mecca for reconstruction and health.

While I am an earnest advocate of early and energetic medication in syphilis, I think that the end is best attained by slow and persistent efforts, and that high-pressure treatment is productive of harm. This is well shown in the following case :

Case I.—A man, aged thirty-seven, descended from perfectly healthy parents, in vigorous health, and weighing one hundred and eighty pounds, contracted syphilis in September, 1888. In October he noticed a chancre on his penis and went at once to the Hot Springs. The nature of this lesion being in doubt, nothing in the way of general medication was done for a time. On the 26th of November he was found to be covered with a roseolous and papular syphilide, and that the ganglia over the body were much enlarged. He was immediately ordered double rubbings with mercurial ointment, to take ten grains of the iodide of potassium thrice daily, and to take a daily bath of a quarter to half an hour's duration at a temperature of 100° or 101° F. He had the double-quantity inunction made upon him for six days, during which time he was liberally dosed with opium and essence of ginger to lock up his bowels. Being unable to stand this very active treatment the inunctions were omitted for a few days, but during all this time the quantity of the iodide of potassium was being increased daily. The inunctions were resumed daily after his bath, in the ordinary dose generally administered, until January 7, 1889, when he had taken in all thirty-six inunctions. At this time he had reached nearly three hundred grains of the iodide, in divided doses, daily. While he was under treatment he had every hygienic advantage which could be obtained at the springs. On his departure he was told in a general way that later on he might need treatment, but he reasoned to himself, as very many do, that he had had a very thorough course of treatment, and he felt that the baths must have had some mysterious but salutary effect. On his arrival home in the South he felt tolerably well, though he weighed only one hundred and forty-five pounds, having lost thirty-five pounds during his sojourn at the springs. He remained without treatment, feeling secure and confident, for a month, when he began to realize that he was far from well. At this time a general papular eruption, with much malaise and debility, appeared. He then was treated indifferently for many months and grew progressively worse. He came to me October 1, 1889, in the following condition: On the forehead, near the hair border, was a semicircle of papular tubercles, on the left ala nasi was a large tuberculated patch skirted by a number of scaling papules; on the right wrist was a very large tuberculated mass, nearly an inch in thickness; over the right shoulder was a group of tubercles as large as one's hands; over the legs were small groups of tubercles, and there was gummatous infiltration into the hard palate (bone and mucous membrane), and into the velum palati. His weight was about one hundred and forty pounds, his strength was much lessened, his facies was sallow and haggard, and his general morale was greatly depressed. He was put upon tonic treatment, received regional mercurial medication for his lesions, and took in irregular alternation both mercurial baths and the mixed treatment in full strength. He now (January, 1890) claims that he is very well, weighs one hundred and eighty pounds, is attentive and zealous in the discharge of his duties, enjoys life, and confidently looks forward to a ripe and happy old age.

This case is one of many similar ones which have come under my notice after a sojourn and treatment at the springs during the exanthematic period of the disease. It carries with it important lessons. It shows us the heroic routine, or as I have heard it called, the "lightning course of treatment," which is often pursued there. While I am an ardent advocate of a full-measure, well-ordered course in the early period of syphilis, I must protest against such indiscriminate medication as was pursued in this instance. I know full well that under the conditions which exist at the springs larger quantities of mercury can be used than are possible when the patients are at home; but my observation teaches me that when thirty-six inunctions, six of which are of double strength, are administered in a period of forty-three days, that though the visible lesions of syphilis may disappear, the patient's ultimate condition is made worse and often rendered precarious. It is this seeming necessity to do so much in a very short time, and to crowd in one month a course of treatment which should be extended over two or three, that in my judgment really works harm to the patient rather than good.

In its early stages syphilis should be treated thoroughly and persistently, but we should never resort to high-pressure principles. Let us do all we can to bring our specific agent—mercury—to work as directly as possible on the new infectious material which permeates the patient's system, but let us not try to work a revolution. Had this treatment administered to this man been interrupted by intervals of a few or several days, its outcome would have been beneficial.

Special stress should be laid upon the fact that during treatment this patient was actively dosed with preparations of opium in order that the inunctions should not cause diarrhœa. Such a practice is to my mind very reprehensible. No man's nutrition is in a normal state whose system is under the influence of opium, and I claim that we can never determine the exact condition of a patient nor the progress we are making with our anti-syphilitic remedies while he is in the power of that drug. I have seen many patients like the one whose history I have just narrated, who have, figuratively speaking, gone to pieces very soon after they had left the exhilarating atmosphere of, and the conditions which prevail at, the Hot Springs.

Then, again, there is another very important consideration regarding syphilitics at the date of the onset of their malady. Though they may have been deeply impressed with the gravity of their condition, they often become lulled into a feeling of false security after a sojourn at the springs. I have seen many patients who in later years have suffered severely from syphilis, who on the breaking out of their disease had hastened to the Hot Springs. They there underwent a course of treatment and the evidence of their disease vanished. Thinking that besides the skill of man they had, as we may say, supernatural aid from the wells of nature, many have gone away with a sense of happy security, imagining themselves cured; others have thought that a similar sojourn a few months or a year later was all that was necessary; while others again have decided to apply for medical aid only if they should notice later manifestations of their disease. This glamour of security and health conferred by the mystery of the waters has brought many a man to invalidism and death through some late-appearing cerebral or visceral lesion of syphilis.

In justice to a number of the many eminent and skilled

practitioners at the springs, I must here say that I know personally that they have impressed many of their patients with the fact that the early course of treatment followed there should not be looked upon as final, but as only the beginning of their efforts to attain a perfect cure.

It is only fair to state that there are practitioners at the springs who do not begin the treatment of early syphilis fully in the high-pressure manner detailed in the foregoing case, since many of them I know do not thus prematurely use the iodide with the inunctions, but owing to the exigencies of the cases and to the limited time allowed for treatment, high-pressure principles largely prevail, and, as I have said before, they are not productive of ultimate benefit.

All fair-minded men, however, who have much to do with the treatment of syphilis, must certainly admit that in certain cases and in certain conditions a sojourn, under proper medical care, at the Arkansas Hot Springs is very often followed by the most gratifying results. It certainly must not be thrown up as a reproach to these skilful men at the springs that they treat in the routine way such a large variety of cases, since they have no option but to do so; and when such large numbers apply for treatment there is not much latitude for variations of method or choice of remedies.

I myself have sent many cases to colleagues at the springs, and have never had occasion to regret it, and I am glad that as a therapeutic resource we have these springs at our command in cases of urgency and need. While in general we can readily handle the cases of ulcerating syphilides, including the impetigo form, the ecthyma form, the rupial and the serpiginous, we certainly do find instances which are rebellious and which improve wonderfully at the springs. In these cases, however, we have usually, as complicating conditions, anæmia, debility, mal-assimilation, in which event specific medication is more or less slow or impotent in its working. Then, again, many of these cases have run the gamut of mercurial and iodide of potassium treatment, and these remedies then act as depressants, rather than as anti-syphilitics. In such cases the change of scene and air and the baths are of inestimable value.

The matter may be summed up in this way: In many cases where cachexia, due to any cause, and intolerance of the usual specific medication are found to exist and the activity of the syphilis still persists, treatment at thermal springs is indicated.

In many instances of gummata in broken-down subjects the baths are often of great value, and I have seen gummatous infiltration in the throat much benefited by the treatment used at the Hot Springs.

The osseous and articular lesions of syphilis may only be temporarily benefited in Arkansas, but late syphilitic rheumatism, rheumatic conditions complicated with visceral disease, combinations of gout and syphilis, late syphilitic cachexia without visible lesions, and the generally broken-down state of old syphilitics addicted to alcoholic and other indulgences are all frequently much benefited and some cases thereafter enjoy fairly good health.

Then, again, when, owing to the usual causes already spoken of, syphilis does not go on auspiciously to its extinction, a sojourn at the Hot Springs is often of decided value for its moral, as well as its physical effects. Such patients when at home live in a rut, and while they perhaps keep at their daily affairs, they are depressed and perhaps more or less despondent. Change of scene, of air, of habits and customs enliven them, while previously the treadmill of their existence had made life burdensome.

In persistent cerebral and spinal affections of the most varied character due to syphilis, and the various morbid states and dyscrasiæ which so commonly complicate it, protracted sojourns at the Hot Springs are often productive of marvellous results. In these cases very often the tolerance of anti-syphilitic agents, which are so necessary to relief and cure, is obtained, and patients are often rescued from invalidism and death. Had I the space at my command I could recount many histories in proof of this statement.

But there are still other considerations offered by the treatment pursued at the Hot Springs. Many cures are there made for the reason that mercury is not withheld from the sufferer as it had been at home. Many of the Hot Springs physicians are alive to the fact that the methods of treatment pursued by many surgeons in the large cities are faulty. These latter often fail to cure their cases for the reason that they use mercury in too small quantities. They do harm with the drug rather than good; they do not eradicate the disease, but by their timorousness and want of vigorous treatment induce a condition of hydrargyrosis—a mercurial cachexia. I have seen many instances of this complication. At the springs, after proper preparatory treatment, they receive mercury liberally, and it acts upon them physically and morally like the grace of God. This fact to my knowledge will account for many seemingly surprising cures made at the Hot Springs.

Then, again, there are teachers who inculcate the doctrine that mercury is only beneficial in the early part of syphilis, let us say in its first year. After that it is by them taught that its function is ended and the era of iodide of potassium begins. This fallacious doctrine often works sad havoc on patients, and they hie them to the springs to regain their health and to get their sovereign panacea, and they get it. This is no such specious doctrine taught in Arkansas. The eminent men there know that mercury alone or in combination with the iodide of potassium is beneficial, as a broad rule, in all stages of syphilis, and they do not withhold but often give it with a lavish hand. They do not sit down when a case is before them and with pencil and paper cipher a grain of a mercurial salt into fifths or sixths, or revolve in their mind the minimum or maximum dose; they see the exigencies of the case and lead off on a full dose and watch events. This to my knowledge has been productive of surprising results to the patients many times. If the same general plan had been followed at the patients' homes, they would not have had the necessity of knocking at the Hot Springs surgeon's door and of begging for relief.

In like manner in many instances the administration at the springs of iodide of potassium in large and increasing doses has cured cases which languished in suffering and disease at home because only small doses were given. But I think the tendency to minimize the dose of the iodide of potassium is not as widespread among the profession as it is in the case of the mercurial preparations.

In the foregoing paragraphs I think I have shown that the successful treatment of syphilis at the Hot Springs is in many instances due to the derelictions and shortcomings of the home physicians who were imbued with faulty ideas as to the dose of mercury necessary for cure, and often to the method of use.

I think that in a large number of cases (and I have seen scores of instances) patients have resorted to the Hot Springs for treatment of syphilis because their cases were not actively handled, were not thoroughly medicated, or were treated in a free and easy, happy-go-lucky manner, or were treated in a too stereotyped way at their homes. But here it is well to remember that many cases of syphilis do badly or go wrong in consequence of the apathy and want of care and the indulgences on the part of the patient.

Let us further consider the errors in treatment which have resulted disastrously to the patient and have caused him to resort to the Hot Springs. I shall in this connection only state facts which have come under my own observation.

The use of iodide of potassium in the early stage of syphilis, particularly in large doses, is often followed by the most distressing and aggravating results. Early in

syphilis especially this agent is strongly contraindicated, for the reason that then the skin and mucous membrane are in a very irritable state, prone to exudative inflammation and to ulceration. Now in many patients, particularly those afflicted with an idiosyncrasy to this drug, dermal congestions and follicular inflammations of the skin and mucous membrane are frequently produced by it. As a result of these inflammatory foci, the neighboring lymphatic ganglia also become much inflamed, and severe complications are often the result. Then, again, it is not uncommon in the early months of syphilis to see the follicular papules and pustules, flat papules and plaques, induced by the iodide of potassium on the subsidence of the acute inflammation, become transformed into lesions which the most skilful observer would take to be undoubtedly syphilitic. In other words, the iodide of potassium produces in syphilitics inflammatory foci which may become transformed into true specific lesions. Then, again, these inflammatory lesions of skin and mucous membrane often fall into ulceration which may present the physiognomy of classical syphilides.

It is imperative that in early syphilis particularly all sources of irritation of the skin and mucous membranes should be avoided and prevented, and it is especially prejudicial to the patient to cause him to swallow a medicine which at that time is liable to be followed by such troublesome and often dangerous sequelæ. Further than this, iodide of potassium alone is almost inert in the primary and secondary periods of syphilis, as anyone can readily learn who will try to cause an initial nodule to melt away or a papular rash to fade under its influence. Let me here narrate two cases which were treated in this reprehensible manner and in which it was thought by some that cure could only be obtained through a sojourn at the Hot Springs. These cases are reported to show the ill effects of the iodide when used early in the disease, and also in order to demonstrate the fact that even when syphilis is thus disadvantageously complicated it does not follow that they cannot be cured at home.

While I am anxious to state in all fairness and justice the good results which may be obtained at the Arkansas Hot Springs, in bad and complicated cases of syphilis I certainly must claim that in the vast majority of cases our methods and resources at home are equal to all demands for relief and cure.

As nothing has been written thus far with the end in view which I aim at, I think no apology is necessary for the following histories:

Case II.—A man, aged twenty-four, had hard chancre and inguinal adenopathies followed by a general roseola. He was ordered iodide of potassium in eight-grain doses four times a day. In four days a papulo-pustular eruption appeared on back, chest, arms, and outer thighs. The medicine being continued, large papules and urticarial wheals appeared over the body and extremities. At this time the itching and burning became so severe that, as a result of scratching, most of the lesions were converted into active ulcers, which were seated on large plaques of hyperæmic and œdematous skin. When first seen by me he was in a deplorable condition, movement of the arms was difficult and painful, and locomotion was much impaired by the swelling and soreness in the legs. His digestion was bad, his mouth and throat sore, and his nutrition going from bad to worse. The ganglia over the whole body were much tumefied and somewhat sensitive. He was brought to me for relief, with the suggestion that perhaps he had better go to the Hot Springs. He was sent to the sea-side to recreate and to take hot salt-water baths. Internally he took quinine and nux vomica and easily digestible, nutritious food. Locally he was treated with daily inunctions of thirty grains of an ointment composed of equal parts of blue ointment and cold cream. About once in four days ninety grains of the bichloride of mercury were added to his regular thirty-gallon bath of hot salt water. In six weeks he returned with good digestion, much increased weight, vanished dermal lesions, and with an aptitude for the ingestion of the necessary daily quantity of mercury for the proper continuance of his treatment. In due time he was cured.

Case III.—A man, aged twenty-one, having such early secondary manifestations as roseola, rheumatoid pains, cephalalgia and general adenopathy, was promptly put on the use of iodide of potassium in ten-grain doses, thrice daily. His roseola became deeper in hue and to a large extent markedly papular in character. His throat became red and swollen, his tongue thick and painful, and he lost his appetite and his strength failed. In addition, he had swelling and redness of the eyes, and nasal obstruction. In a few days ulcerations appeared in the pharynx and on the tongue, and very soon the submaxillary and cervical glands became markedly swollen and tender. Upon the extremities the syphilitic lesions developed into inflammatory plaques, and the burning and itching sensations were very severe. This man also had an impression that his only salvation was to be found at the Hot Springs, but circumstances compelled him to stay in New York. His mouth and pharynx were carefully attended to, his digestion was improved and his strength increased by proper medication. Locally he took at first alkaline and bran baths and then bichloride baths, and was rubbed freely with a mild calomel ointment every day. This treatment, which was aided by an occasional outing in the country for a few days, worked auspiciously, and in ten weeks he was free from his pharyngeal and dermal trouble, though his ganglia were still enlarged. He, however, was in a sufficiently good condition to begin and to continue a proper anti-syphilitic treatment.

In this connection I may briefly report one more case, showing the baneful effects of iodide of potassium when badly used late in syphilis.

Case IV.—A woman, forty-three years of age, had syphilis ten years before, for which she was treated indifferently for less than six months. She suffered for years from a succession of lesions of the skin, bones, joints, and mucous membranes, for which she spasmodically underwent treatment. In the tenth year of her disease she was attacked with a large tubercular nodule in the skin, over the left nasal bone. She was promptly put on iodide of potassium, beginning with ten-grain doses four times daily, which was quite rapidly increased. When she had taken this agent for about a week, it was noticed that her face became red and swollen, particularly near the nasal lesion; the dose, however, was continued and increased. Then large inflammatory plaques, nodules, tubercles, and hæmorrhagic bullæ appeared all over the face, scalp, and neck, yet the dose was progressively increased, as the local lesion did not yield. Then, when she was taking nearly four drachms of the drug daily, her hands, arms, and feet became similarly affected. In this woe-begone condition, with her head much enlarged, her throat, hands, arms, and feet swollen and painful, with utter loss of strength and digestion, she was brought to me. By means of tonics, change of air, alkaline baths, bichloride baths, friction with mild mercurial ointment, and particularly by means of a local mercurial treatment to her facial lesion, she was restored to health in rather more than three months.

If in this case active local mercurial medication had been applied to the lesion over the nasal bone, and a mild mixed treatment administered internally, it would have rapidly disappeared without any untoward complication. But the iodide was given blindly, regional treatment was not thought of, and the patient came to grief.

I have been much impressed, of late years, with the almost entire want of appreciation, and often ignorance, on the part of physicians, of the inestimable value of local or regional mercurial medication. The foregoing case exemplifies this point admirably, and I have seen many other cases of lesions of mucous membranes of the skin, of the bones and the joints, and of the brain and spinal cord, in which patients have been brought to a condition of cachexia, and even marasmus, by ill-advised heroic in-

ternal medication, when a well-directed, energetic local or regional treatment would have caused the subsidence of the lesion or a mitigation of the trouble, and when proper internal medication, simultaneously administered, would have been accessorily beneficial.

To my knowledge many a case has gone to the Hot Springs in a deplorable condition, in consequence of the over-dosing used to cure a local syphilitic infiltration or hyperplasia, which would have readily yielded to regional treatment, combined with a mild and salutary internal system of medication. The profession have yet much to learn in this direction in the treatment of syphilis, and it will be well for humanity if the lesson is learned early and thoroughly.

There is another reason why syphilitics often do very badly and, failing to get relief at home, seek for it at the Hot Springs. In my judgment, in the reaction from the large doses of mercury given by our forefathers, we have gone to too great an extreme—we have made too big a jump. The treatment of syphilis will never be on a permanently satisfactory basis as long as we blindly persist in the fixed and attenuated doses which are advised by many. The teaching of some authors carries with it too much arithmetic in the matter of the dose, and too little attention to the necessity of study and observation of the patient. No iron-clad rules can be laid down for the dose of mercury, generally, since no two cases are alike in yielding to a certain quantity. All we can do is to give approximative ideas. Therefore I say that we should not, as many do, content ourselves with the thought that our patient is taking, say, three-fifths of a grain, or four-fifths, or even a grain, and hope that all will be right. We should see what our agent is doing, we should watch the patient continually and closely, and, if the lesions and symptoms do not clear up, increase the dose until they do, or this failing, we should substitute some other method of administering the mercury. I have seen many cases do badly, and then physicians remain content and placid, thinking that they are giving the proper amount of the drug, and that in time, with its continuance, all would be well. With the inauguration of attenuated dosage, and a very prolonged treatment of syphilis, an easy and happy-go-lucky state of mind has taken hold of many physicians. A number of them seem to think that if their arithmetic of dosage is all right and they keep on, time will work a cure. It is far from my purpose to imply that I advise an heroic or overwhelming use of mercurial salts, for I do not. My position is that the patient is the problem to be studied, and that the question of dose should arise out of the deductions derived from its study, and that all iron-clad formulæ of stereotyped doses are unscientific, and liable to be productive of failure or disaster. Therefore, I say that we should watch and guard the mouth, throat, and alimentary canal of our patients, and remove from them all irritation and sources of irritation in order that our agent may be readily assimilated.

Nothing can be more fallacious than the dogmatic laying down of fixed doses which are based on the condition of the mouth, tongue, and alimentary canal, since these are often in an abnormal state which is easily rectified, and again when irritated can readily be brought back to health by appropriate local treatment. In a great majority of cases, proper attention to the mouth, pharynx, and intestinal canal will be followed by a satisfactory tolerance of mercury taken by the mouth. If the suggestions contained in the foregoing paragraphs are heeded, there will not be many cases of mercurial intolerance seen, and few patients will have to journey to Arkansas to obtain that tolerance.

Another source of failure in the treatment of syphilis, and one which is frequently productive of great distress, and even disaster, lies in the fact that too much reliance is placed by some on the effect of mercury administered by the mouth. The treatment of syphilis should be based on broad grounds and not pursued in a narrow gauge. The student should be taught that while mercury given by the mouth should be the regulation standard of treatment, that thus administered the agent may fail, that circumstances and conditions may arise in which it is inoperative and even prejudicial, and that then there are other methods of great certainty and value to fall back upon.

Both in hospital and private practice I constantly see syphilitics who have done badly, and whose cases have been considered extremely rebellious and even hopeless by themselves and their physicians, which can in a short time be brought to a satisfactory state by a judicious modification of the treatment, and by the adoption of various expedients which their history suggests. I can best illustrate this point by the brief recital of three cases, each of which carries with it an important lesson.

Case V.—A woman, aged twenty-two, thin and sickly, had a hard chancre late in July, 1889, which was followed by an erythematous syphilide and other early manifestations in the first part of September. Under protoiodide of mercury, iron, and quinine, and careful hygiene, the rash disappeared and she was tolerably well early in October. Having taken the mercury in quarter-grain doses thrice daily, until the first of November, as there was no contraindication, the drug was increased to a grain daily, in four doses. It was noted that all along she progressed only fairly as to her general health and that her symptoms yielded rather slowly. While under all the mercury which was deemed prudent to give her, during November she lost flesh and strength, and her digestion became impaired. During this period a small miliary papular syphilide appeared on the forearms, and from there spread over the whole body, and the ganglia generally became much enlarged. Noting that the case was one of a class which we so constantly see, in which mercury by the stomach failed to control the disease and tended to induce malnutrition, it was for a week suspended and tonics only were given. Then inunctions of thirty grains of strong mercurial ointment were ordered to be made daily, particularly over those portions of the regions upon which the papules were most copious. With the occasional omission of a day or two this inunction treatment has been kept up until to-day (January 11, 1890), having been begun on the 27th of November. She is now cheerful and happy, and has gained eight pounds in weight. Her digestion is good, her strength satisfactory, and her assimilation and nutrition in excellent condition. The papular syphilide, over which internal medication had no control, is nearly effaced, and the enlargements of the ganglia are very much less extensive.

Such cases as these are far from uncommon, particularly in hospital practice. They cause physicians much trouble and they tend to convince many that mercury is inert, even prejudicial, in the treatment of syphilis. It is not only the cases of miliary papular syphilide, but those having any and all forms of syphilitic erruption or manifestations, which are liable to go wrong in the manner exemplified in the foregoing case. I have many times been consulted by physicians about syphilitics, and by patients under these conditions, concerning the propriety of a sojourn at the Hot Springs. As a rule, the cessation of internal mercurial medication and the adoption of the inunctions, or the hypodermic and the fumigation treatment, combined with a tonic course and general hygiene, is always followed by very gratifying results. A change of air is also of inestimable advantage.

Case VI.—A man, aged thirty-three, rather fat and flabby, enjoying what he considered good health, and deeply engrossed in exacting financial transactions, became syphilitic in July, 1887. His early erythematous rash, cephalalgia, and fugitive pains in bones, joints and fasciæ were dissipated by one third of a grain doses of the protoiodide of mercury taken three and sometimes four times daily. With this treatment iron and vegetable tonics were combined, outings in the country were ordered, and abstention as far as possible from business cares, were advised. In September, while still under treatment and when his general condition was satisfactory, he went upon

a severe spree which lasted four weeks. On emerging from this he was found to have a dense, hard, papular syphilide over the face, the shoulders, and the wrists, on the palms and soles, and ulcers in the throat and on the tongue, with a scattered papular eruption over body and thighs. Very soon he was attacked with syphilitic epididymitis of the right side, the fasciæ over the knees became very painful and thickened, and he had several nodes on the cranium. His appetite was poor, his strength at a minimum, and he was incapable of prolonged mental effort. While temporarily absent from me, a physician began at once the use of the protoiodide in one fifth of a grain doses, three times a day. He thus continued for three weeks until his return to the city. Then he was much debilitated, very pallid, and rather thinner, and saw that he was growing weaker day by day. He was no longer able to take the mercury by reason of gastro-intestinal intolerance, and in fact only the most digestible food could be taken. His physician out of the city had informed him that his only chance of cure and restoration to health was in a prolonged stay at the Hot Springs. Business cares would not admit of a long absence, so he remained in the city, running away to the country at short intervals for a few days. I treated his mouth and throat lesions locally, gave him tonics and surrounded him with every possible hygienic aid. Then I began carefully guarded and mild mercurial treatment, by inunctions chiefly, but when these, for various reasons, could not be used, I substituted hypodermic injections of the bichloride of mercury. The first noticeable changes were his returning appetite and his increased strength, then his mental calibre grew better and he lost his despondency and apathy. Slowly and gradually the lesions of the bones, fasciæ, and of the epididymis subsided, each one of them having received careful regional treatment in the form of mercurial frictions. By the beginning of winter he was free from all evidence of syphilis, except moderate general adenopathy, and after an interval of freedom from antisyphilitics, being tired of inunctions and hypodermic injections, he took the mixed treatment in goodly doses with perfect impunity and benefit.

Case VII.—A woman, thirty-one years of age, became syphilitic three years previously, and suffered from persistently relapsing eruptions of a papular and tubercular character. She followed treatment at intervals in an indifferent and spasmodic manner, occasionally under my direction, and was during this period given to dissipation and addicted to alcoholic indulgence. In the second year of her disease she began to complain of headaches, particularly at night; her nutrition became lowered and her strength impaired. During six months she took medicine, patented and otherwise, at random, and received no relief. As her sufferings continued she sought a specialist in nervous diseases, who informed her that she had congestion of the brain. He ordered bromide of sodium in full doses to relieve her pain, and directed that she should take an occasional hypodermic injection of morphine to induce sleep. In July, 1884, I had seen the patient and diagnosticated syphilitic pachymeningitis, with involvement of the bones of the cranium in scattered spots. The treatment then ordered was not carried out and the patient gradually drifted into the condition just described.

In February, 1885, the patient presented the following conditions: She was much emaciated and utterly abject, and she had no appetite, and had not partaken of solid food for several months. She suffered from continuous headache, sometimes dull in character and again of neuralgiform type. To the touch the scalp was very sore and sensitive, and pressure on a number of spots caused excruciating pain. She suffered from persistent insomnia, and when she awoke from occasional short naps felt wretched, dejected, and in pain. She could scarcely sit up, and if she attempted to walk her movements were of a shambling and shuffling character, aided by the support of attendants or by leaning on the articles of furniture. Her temperature averaged 100 F., and the pulse was frequent and thready. To add to her deplorable state, she had become habituated to morphine, which was administered frequently during the day and night to the amount of about two grains daily. Her husband thought that she should go to the Hot Springs, but he saw very plainly that she could never reach there. At the time of my first visit in February, 1885, the patient had come under the care of my accomplished friend, Dr. C. E. Lockwood, who at once asked my aid in her treatment. The patient was then taking about two drachms, daily, of iodide of sodium, together with varying quantities of bromide of potassium. We at once reduced the quantity of morphia to one-quarter of a grain in two doses daily, and gave a quinine and nux vomica mixture. Then we caused to be rubbed into the sides of the neck, the nucha, and over the painful spots on the scalp, every night, thirty grains of strong mercurial ointment. In two weeks, during which the pain had been severe and the general condition seemingly not much altered, the stomach became more tolerant, and we began the use of iodide of potassium in twenty-grain doses, three times daily. Though we strove hard to keep the quantity of morphine at the quarter of a grain standard, on some bad days we were forced to allow a little more. By very slow degrees, amid much trouble, pain, weakness, and depression, the patient gradually improved. As she bore the daily inunctions very well and there were no contraindicating symptoms, they were kept up with tolerable regularity. Toward the end of March (the patient then being under this treatment about fifty days) evident signs of marked improvement appeared. The appetite was better, and digestible solid food could be taken in sparing quantity, the mental calibre of the patient was stronger, she began to increase in weight, and her general physical condition was better than it had been for a year. Still continuing the iodide of potassium until, in the end, three hundred grains were taken daily, and the inunctions, with occasional omissions, we kept the patient upon tonics and surrounded her with every hygienic advantage. Late in April the use of morphia, which had been slowly and painlessly reduced, was abandoned, and there then was no drawback to prompt recovery. We continued the internal use of the iodide and the guarded application of the mercurial frictions until late in June, when the patient declared herself quite well, and refused all further medication and restraint. The pain in the head degenerated to soreness, and this gradually passed away.

This woman has not since suffered from any manifestation of syphilis, and can hardly be said to have followed systematic treatment since June, 1855, yet in this interval she has committed many mistakes in the too free indulgence in alcoholics.

In conclusion, I may say that with increasing care and precision in clinical examinations, and proper adaptation and modification of the dose of antisyphilitic remedies in the treatment of syphilis, and with an armamentarium rich in resources and adaptable methods, the physician will less and less frequently experience the chagrin of having his patients elope to the Hot Springs of Arkansas.

Honoring a Scotch Surgeon.—According to a notice which appears in the *Gazzetta degli Ospitali* for March 23d, the governing body of the great school of practical medicine and surgery, the "Policlinico Umberto I.," now in course of erection at Rome, invites sculptors to compete for the commission to execute two bas reliefs in Monte Alfilano stone. These bas reliefs are to adorn the principal elevation of the medical and surgical departments respectively. The subject of the former is to be Morgagni teaching his pupils the investigation of the seats and causes of disease. He must be represented as the founder of the naturalistic method, and not as a mere dissector of dead bodies. The subject of the other design is to be Sir Joseph Lister in the act of demonstrating his system of dressing wounds, which the committee calls "the greatest conquest of modern surgery."

THE PENDENT LIMB IN THE TREATMENT OF JOINT DISEASES OF THE LOWER EXTREMITY.[1]

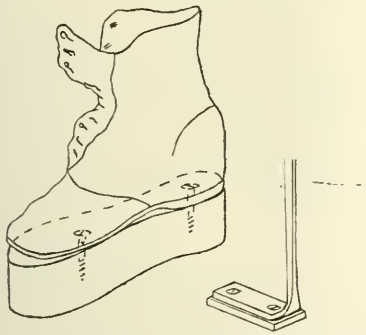
By A. B. JUDSON, M.D.,

NEW YORK.

Cases of Articular Osteitis.—The following figures, drawn from the last annual reports of two orthopædic institutions[2] illustrate an interesting fact, contain an important pathological doctrine, and enforce a practical lesson: Hip, 558; knee, 207; ankle, 64; total, 829. Shoulder, 7; elbow, 16; wrist, 3; total, 26.

It appears that in a single year eight hundred and twenty-nine cases of disease occurred in the large joints of the lower extremity, while twenty-six cases occurred in corresponding joints of the upper extremity.

That this disproportion exists is a most interesting fact, one that has been under our eyes year after year, and only lately properly recognized and emphasized. The pathological doctrine embodied is that inflammation of the bony structures of a joint is readily and spontaneously resolved when favorably situated, as in the upper extremity, where the part affected is absolutely exempt from the violence which falls on the structures of the lower limbs in standing and in locomotion. The practical lesson is the precept that in the very earliest incipiency of disease



of any of the joints of the lower extremity, the weight of the body should be taken off from the affected limb until the inflammation is resolved, though it may take months and years. By the arts of mechanical surgery the affected member should be made constantly pendent, and as little liable to strike the ground or receive the corporal weight as the arm, which swings free in locomotion, and has never known the burden of the weight of the body.

What application of mechanical orthopædic surgery can be best made for this purpose? Crutches and a high sole on the well foot are a ready solution of the problem; but consider the difficulties, one of which is found in the fact that the patient, usually a child, will lay crutches aside, and no amount of persuasion or discipline can keep them in use during the long periods in which the general health and freedom from pain obscure the serious nature of the affection.

This difficulty disappears with the use of the simple device known as the perineal or ischiatic crutch, which retains its place without the aid of the hands and under the clothing. That its use leaves the hands and arms free, and that it is inconspicuous, gives it a great advantage over a pair of crutches; but its chief superiority lies in the fact that by its use the weight of the body falls on the ischiatic tuberosity, a part of the anatomy which is accustomed to bearing the weight in the ordinary sitting posture. The construction of the axilla is but little adapted for sustaining such a weight. The loose joint which the shoulder makes with the trunk, and the presence, in just the wrong place, of the brachial and axillary vessels and nerves, make the use of a pair of crutches sometimes painful, and generally awkward.

When we consider, on the other hand, the stability of the union between the os innominatum and the vertebral column, the basic position of the os innominatum in the skeleton of the trunk, and the fact that it is designed to bear, and most of the time does bear, the weight of the greater part of the body in sitting, standing, walking, and running, it becomes clear that here, if anywhere, should be applied an artificial support for the relief of a disabled lower extremity.

The ischiatic crutch[1] described and exhibited on previous occasions, with its perineal strap applied to the tuberosity and ramus of the ischium, is simple in its construction and fully insures a pendent limb, whether the joint to be protected is the hip, knee, or ankle. It does not interfere with the ordinary activities of childhood, and it is practically easy with this instrument to obey the precept above referred to in regard to making the limb pendent from the beginning to the resolution of articular osteitis.

Two or three practical points should be attended to. The upright should be strong and light, and these qualities may be secured by a *single* perineal strap which brings the weight of the body more directly over the supporting column, which is the upright portion of the apparatus. The pelvic band should be worn at a level below the anterior iliac spine and above the trochanter, a position in which it may be held if a short perineal strap is used. At the lower end of the apparatus it will be noticed that there is a wide departure from the customary arrangement of feet and shoes. On the affected side the splint, and not the foot, reaches the ground. I have found the method of shoeing the splint, which is shown in the cut, both convenient and economical. If sole leather of the very best attainable quality is used, it lasts a long time and the expense is small. On the well side the necessity of a high sole has been the cause of vexation and expense, both of which I have partially reduced by the use of a wooden shoe, or *sabot*, constructed and fastened on with screws in the manner shown in the cut.

[2] The New York Hospital for the Ruptured and Crippled, and the New York Orthopædic Dispensary and Hospital.

Mr. Gladstone on the Fortunes made by Medical Men.—At the opening of the new Medical College building in connection with Guy's Hospital, Mr. Gladstone made an address in which he referred among other things to the late Sir William Gull, and said: "I am delighted when I hear of the creation of great fortunes in this country that are not merely commercial. It is an excellent thing that large fortunes are made in commerce, by the handling of money, by the supply of the country with material goods; but it is desirable that their power and influence should be qualified by the creation of other fortunes, such as now, almost for the first time, we find beginning to be created by medical men. I rejoice to think that the medical man, who spends his talent and strength as freely in the performance of his duty as any member of any other profession, will be able to make a competent and even large provision for his family. Another point upon which I congratulate the profession is its independence. It does not rely on endowment, but on its own exertions directed to meeting human wants. There is no great profession which has so little to say to the public purse, and which so moderately and modestly dips its hand into that purse. It is not only in the interest of the public, but of the profession itself, that it is eminently self-supporting; and, rely upon it, that that principle of self-support does much to maintain its honor and independence, and to enable it to pursue its stately march in the times that have come and in the times that are coming, to form its own convictions, to act on its own principles without fear or favor, for the general benefit of mankind."

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, April 26, 1890.

DEATH AND THE DOCTOR.

DR. M. BIRNBAUM, of Toerpin, has made a most elaborate statistical study of the mortality statistics as they pertain to the lives of physicians. The figures he gives have a deep personal as well as scientific interest, and although they are far too extensive for us to quote in any detail, some of the facts which he presents may be given to our readers here.

The subject of the mortality rate, the expectation of life, etc., among physicians was studied in 1865 by Gussmann, but Dr. Birnbaum has collected much more complete data; these include facts regarding 2,000 deaths among German physicians from 1881 to 1891, and the facts as to age of 15,000 physicians given in Börner's Imperial Medical Calendar.

First as regards the age of the living members of the (German) medical profession, we find the following:

Age.	Number.	Per Cent.	Age.	Number.	Per Cent.
25–29	3,180	21.20	60–64	645	4.31
30–34	2,157	16.78	65–69	511	3.40
35–39	2,054	13.69	70–74	395	2.63
40–44	1,764	11.76	75–79	228	1.52
45–50	1,476	9.86	80–84	86	0.57
50–54	1,076	7.77	85–89	28	
55–59	1,026	6.84	90–93	9	

From the above it will be seen that among 15,000 physicians the number steadily falls in each half decade. The age at which there are the most doctors is 27. Half the physicians are under forty and three-fourths are under fifty years of age. The fall in numbers is slowest from 50 to 60, and fastest in the next decade from 60 to 70. The lesson is that physicians should beware of overwork after they reach the age of sixty. Relatively, fewest physicians die at the age of 43 and 44. Physicians do not reach extreme old age so often as does the average population. Among 15,000 persons of all classes above the age of 25, about 30 should pass the age of 95 and 180 the age of 90. Not a doctor among Birnbaum's 15,000 had reached the age of 94.

Taking, now, the 2,000 cases of deaths of medical men, it is found that between the ages of

25 and 35, 12.00 per cent. die
36 " 45, 13.15 " "
46 " 55, 16.50 " "
56 " 65, 20.70 " "
66 " 75, 23.85 " "

The percentage then gradually increases. The greatest number of deaths occurs, however, between the years sixty-six and seventy-five, while the most fatal half decade is between sixty-six and seventy years. Taking the yearly mortality-rate among 15,000 physicians, it is found, on an average, to be 2.24 per cent.; or, in other words, one doctor, on the average, among forty-four, dies annually.

Birnbaum's tables make the expectation of life of the physician as follows.

At the age of 25	62.11
" " " 35	63.09
" " " 45	64.83
" " " 55	67.75
" " " 65	72.68

This makes the expectation of life for the physician a little below that of the average population, but not very much

As to the average duration of life of physicians, Birnbaum quotes Neufville's tables as follows:

Clergymen	65.7	Merchants	56.71
Teachers, Gardeners, Butchers	56.8	Lawyers	54.2
		Physicians	52.2

Among 238 cases of deaths among medical men he finds the following causes:

Infectious diseases	16
Chronic pulmonary diseases	22
Acute pulmonary diseases	21
Chronic heart disease	30
Apoplexies	40
Brain and spinal cord diseases	20
Cancer	19
Liver disease	7
Abdominal disease	5
Bright's disease	8
Diabetes mellitus	3
Surgical diseases and injuries	5
Deaths from violence	11
Old age	9
Other diseases	22

In looking over the above no one can fail to be struck with the fact that an unusually lare number of deaths are such as come from exposure and severe mental and physical labor, while comparatively few deaths are of the kind brought on by intemperate living in the sense in which that word is ordinarily employed.

The doctors are plainly a hard-worked and not very long-lived race.

WHY PHYSICIANS SHOULD NOT ADVERTISE.

A RECENT issue of the *Chicago Tribune* containing a marked editorial with the above heading has been sent about to the medical journals. The article, according to the *Northwestern Lancet*, is inspired by the action of the Alumni Association of the College of Physicians and Surgeons of Chicago, in dropping from its roll of members, a Dr. Brinkerhoff, who insisted upon advertising in the daily papers that he was possessed of special skill in the treatment of a certain class of diseases. The *Tribune* decides that advertising by physicians is proper and indeed desirable, in order to let the public know where the highest skill is to be found. It inveighs against the "old and absurd custom" of a medical society's not allowing its members to advertise, and a reporter in another part of the paper refers contemptuously to "old fogy ideas" and the "musty and silly code of ethics."

Our contemporary the *Northwestern Lancet* presents most vigorously and logically the reasons why physicians should not advertise themselves as possessing special skill. These are that the public cannot judge of the

physician's skill or honesty, as they can judge of the quality of material goods, while, at the same time the patient often has at stake his health and life when he sets out to secure medical aid. If this is not as advertised, he cannot return the goods and get the money refunded, but he must suffer the consequences of unskilfulness or dishonesty. Beyond all this, it must be remembered that medical services are personal services, and that the doctor's skill is in a sense a part of his own individuality. No self-respecting man could possibly publicly advertise that he was the greatest and most successful specialist in a certain class of diseases, any more than he could announce that he had the biggest brain or the noblest moral nature of any man in the State. We do not find that editors, who sometimes think that doctors ought to advertise, ever themselves adopt this practice, and yet we have known of editors who needed papers to edit or journalistic work to do.

The limits of medical advertising before the public are announcements of cards and addresses, while some think that the additional announcement of a special limitation of practice is legitimate.

STATE MEDICAL EXAMINING BOARD.

THERE seems a very good prospect that the bill to establish triple examining boards, regular, homœopathic, and eclectic, will become a law. If so the law will be enacted against the wishes and protest of the vast majority of the physicians of this State. The creation of three distinct examining boards is a clumsy, unnecessary, expensive, and pernicious contrivance. If each board does its work faithfully the examinations will be practically the same in anatomy, physiology, chemistry, surgery, obstetrics, and pathology. The only differences will be in therapeutics, and one board could arrange to vary its examinations here. Furthermore, there are the best of reasons for seriously fearing that one or more of the boards will not make its examinations properly stringent, and that the standard will be allowed to fall very low. The Eclectic Board, for example, will not feel like putting on the official record the fact that they "pluck" a larger per cent. than the regular board. Yet the standing of eclectic medical colleges and their means of teaching are decidedly inferior to those of other schools.

We sincerely hope that if the legislature is so unwise as to pass the triple-board bill, the Governor will veto it.

News of the Week.

Preliminary Programme of the Sections of the International Congress.—The following is the preliminary programme of the various sections: I. *Anatomy:* 1. The Convolutions of the Brain. 2. The Present State of the Doctrine of Nucleus Segmentation and Cell Division, with special reference to the Directing Bodies, the Spheres of Attraction, and the Accessory Nuclei. 3. Histogeny and Connection of the Nerve Elements. Sectional Secretary: Professor Hertwig, 34 Maassenstrasse, Berlin, W. IV. *Pharmacology:* Sectional Secretary: Dr. Oscar Liebreich, 34A Dorotheenstrasse, Berlin, N. W. VI. *Diseases of Children:* 1. Intubation of Larynx, J. O'Dwyer, New York. Sectional Secretary: Professor Henoch, 8 Bellevuestrasse, Berlin, W. VIII. *Obstetrics and Gynæcology:* 1. Antiseptics in Midwifery, introduced by Dr. Galabin, London. Professors Stadfeldt, Slavijanski, and Fritch will take part in the discussion. 2. Artificial Premature Labor, introduced by Dr. Thomas Parvin, of Philadelphia. 3. Vaginal Extirpation of the Uterus, introduced by Dr. Williams, of London. 4. Electrolysis of Myoma, introduced by Apostoli, of Paris. Sectional Secretary: Dr. A. Martin, 2 Moltkestrasse, Berlin, N.W. IX. *Neurology and Psychiatry:* 1. Surgery of the Central Nervous System, by Professor Victor Horsley, M.D., London. 2. The Traumatic Neuroses, by Professor Schultze, M.D., Bonn. 3. The Pathological Anatomy of Dementia Paralytica, by Professor Mendels, M.D., Berlin. Sectional Secretary: Dr. H. Laehr, Zehlendorf, Berlin. X. *Ophthalmology:* 1. Sympathetic Ophthalmia. 2. Trachoma. 3. The Influence of the Electric Light upon the Eye. Sectional Secretary: Professor Dr. Schweigger, 6 Roonstrasse, Berlin, N. W. XI. *Otology:* 1. Relations of the Micro-organisms to Affections of the Middle Ear. 2. The Cholesteatoma of the Ear. 3. After-treatment of the Processus Mastoideus when pierced with the Chisel. 4. Pathological Anatomy of the Labyrinth. 5. The Condition of the Ear in Tabes Dorsalis. 6. Hearing Capacity and its Uniform Nomenclature. Sectional Secretary: Professor Lucae, 9 Lützowplatz, Berlin, W. XII. *Laryngology and Rhinology:* 1. Laryngology since the last International Congress in 1887, Dr. Fränkel, Berlin. 2. Diseases of the Accessory Nasal Cavities, Dr. M'Bride, Edinburgh. 3. Cancer of the Larynx, Henry T. Butlin, London. 4. Acute Infectious Inflammations, F. Massei, Naples. Sectional Secretary: Professor B. Fränkel, 12 Neustadtische Kirchstrasse, Berlin, W. XIII. *Dermatology and Syphilography:* 1. Pathology of Pigmentations and Decolorations of the Skin. 2. Chronic Gonorrhœa. 3. The Treatment of Syphilis. 4. Inflammatory Skin Diseases. 5. The Nature of Exanthemata due to Drugs. 6. Lupus Erythematosus: its Nature and Treatment. Sectional Secretary: Dr. Lassar, 19 Karlstrasse, Berlin, N. W. XIV. *Teeth:* The work in the forenoon will consist of practical demonstrations in the Dental Institute, and the afternoons to the discussion of papers. 1. Narcosis with Bromide of Ethyl. 2. Pyorrhœa Alveolaris. 3. Micro-organisms and Decay of the Teeth. 4. Crown and Bridge Work. 5. Bonwill Method of Articulation. Sectional Secretary: Professor Busch, 6 Alexander-Ufer, Berlin, N. W. XVI. *Medical Geography and Climatology:* 1. On the Influence of Tropical Climate on Immigrants. 2. On the Endemic and Epidemic Diffusion of Yellow Fever. 3. Beri-beri regarded from an Etiological and Therapeutic Point of View. 4. Leprosy, with special regard to its Spread by means of Hereditary Transmission and Contagion. 5. On the Geographical Extension of Malarial Diseases. Sectional Secretary: Professor A. Hirsch, 113 Potsdamerstrasse, Berlin, W. XVII. *State Medicine:* 1. The Doctrine of the Gonococcus. 2. On Virile Impotence. 3. The Lung test for Live Birth. 4. Does Sepsis originate after Spontaneous Abortion? 5. Does Moral Insanity exist as an Independent Disease or as a Symptom of other Forms of Mental Alienation? 8. The Proofs of Vitality. 9. The Auto-infection of Puerperal Women. 10. The Ptomaines in Forensic Medicine. 11.

Forensic Experiences of Rigidity in Corpses. Sectional Secretary: Professor Liman, 46A Königgrätzerstrasse, Berlin, N. W. XVIII. *Military Hygiene:* 1. The Antiseptic Treatment of Wounds resulting from the Accidents of Warfare, Generalarzt von Bergmann. 2. Movable Hospitals in Peace and War. 3. Hospital Ships in Naval Warfare. 4. The Organization of the Prophylaxis of Epidemic in the Armies in the Field and at Home. 5. The Sick Lists and Sanitary Reports, John S. Billings, U. S. Army. 6. The Trepanning of the Skull. 7. The Mortality in the Italian Army (1881–88), Dr. J. Sormani. 8. Movable Hospital Barrack for Tropical Countries, Dr. Daubler. Sectional Secretary: Oberstabsarzt Dr. Krocker, 65 Potsdamerstrasse, Berlin, W.

Removal of Large Portion of the Stomach (for Carcinoma) with Gastro-enterostomy.—The patient of Dr. W. T. Bull referred to in RECORD of April 19th has made satisfactory progress, and may now (twelfth day) be considered out of danger. This is the first successful American operation for cancer of stomach, and is the third instance in which, after resection of a large part of the stomach, a gastro-enterostomy has been performed. Billroth reports two cases, the first in 1885, which recovered, and the second in 1887, which died.

An Opportunity to Visit Mammoth Cave.—The following offer of stop-over privileges is made by the Louisville & Nashville Railroad to delegates from the North attending the meeting of the American Medical Association: "All who may attend the meeting can stop over at Mammoth Cave Junction going to Nashville, by notifying our conductor between Louisville and the Junction of their intention to do this; he will then permit them to retain their tickets for transportation on another train from the Junction to Nashville. Before leaving Mammoth Cave, the tickets should be presented to our agent at the Mammoth Cave Hotel, who will endorse them, making them good for passage to Nashville even should the limit have expired. If it is not convenient for all to visit the Cave upon the south-bound trip, we can arrange for such visit when returning from Nashville, but this will not be arranged until the Secretary of the Association notifies the Company that some in attendance wish to make this side trip after leaving Nashville."

Death of Dr. Eisler.—Dr. Morris Eisler, for nearly thirty-seven years a prominent German practitioner in New York City, died last Friday morning, after an illness of several months, at his residence, 176 Second Avenue. He was born in Galgócz, Hungary, in 1818, and when a student of medicine at Buda-Pesth in 1848, he took a prominent part in the revolution. He joined the forces as army surgeon, taking active part in the campaign under General Bem. After the overthrow of the revolution he fled to Leipsic, and subsequently to Paris, in which city he finished his medical studies. Going to London he met Louis Kossuth, at whose advice he came to this country in 1853, and had since been engaged in the practice of his profession in this city. His body was cremated on Sunday morning at the Fresh Pond Crematory. The deceased was a member of The County Medical Society.

The California State Medical Society held its annual meeting in Los Angeles on Tuesday, Wednesday, Thursday, and Friday, April 15th, 16th, 17th, and 18th.

Confederate Army Surgeons.—Dr. Joseph Jones, Surgeon General of the United Confederate Veterans, has addressed a circular to the survivors of the medical corps of the Confederate army, requesting them to meet with the United Confederate Veterans in Chattanooga, Tenn., on July 2d. He asks that they assist in furnishing a history of the medical corps of the Southern army by contributing data on the following subjects: First—Name, age, nativity, date of commission in the Confederate States army, nature and length of service of each and every member of the medical corps of the Confederate States army. Second—Obituary notices and records of all deceased members of the medical corps of the Confederate army. Third—Titles and copies of all field and hospital reports of the medical corps of the Confederate army. Fourth—Titles and copies of all published and unpublished reports relating to military surgery and diseases of armies, camps, hospitals, and prisons. The object proposed to be accomplished by the Surgeon-General of the United Confederate Veterans is the collection, classification, observation, and final publication of all the documents and facts bearing upon the history and labors of the medical corps of the Confederate States army during the Civil War of 1861–65. It is believed that invaluable documents are scattered over the whole land, in the hands of the survivors of the Civil War of 1861–65, which will form material for correct delineation of the medical history of the corps.

The Quarantine against Leprosy.—At a recent meeting of the Vermont State Board of Health, a communication was received from Surgeon-General Hamilton, of the Marine Hospital Service, suggesting that the board, in accordance with the provisions of the law passed by Congress in relation to quarantine against leprosy, appoint an inspector on the border. The Board accepted the suggestion, and Dr. Hamilton, of Richford, was appointed inspector for Vermont.

A Half Century of Dinners.—The Lycoming County (Pa.) Medical Society enjoyed its fifty-first annual banquet in Williamsport, on April 10th.

Charges of Cruelty against Hospital Managers.—A dissatisfied patient and his friends have brought charges against the City Hospital of St. Louis, alleging that the orderlies and nurses are often very cruel in their treatment of the patients, that the food is of poor quality and insufficient in amount, and that the sick are made to do all the work of the institution. The superintendent denies the charges, which were made probably by some self-esteemed individual who did not receive all the attention which he thought his importance in the social scale demanded.

The Prevalence of Rabies.—The *Boston Journal of Nervous and Mental Diseases* states that eight cases of canine rabies have recently been noted in Lowell, Mass., and one case of hydrophobia, in which the man died forty-two days after being bitten, is reported.

A case of hydrophobia is reported in Watertown, Mass.

A case of canine rabies was recently observed in Yonkers, N. Y.

The Republican Valley Medical Society held its annual meeting in McCook, Neb., on March 25th.

Successor of the Late Professor Westphal.—Professor Grashey, of Munich, has been appointed to succeed the late Professor Westphal in the Chair of Mental Therapeutics in Berlin.

The Ladies' Health Association of this city proposes to have a mass meeting April 30th, in order to protest against the condition of the streets. The ladies of this association have accomplished some notable reforms in the past two years. Among these is that compelling all stables in the city to bale the manure and refuse in place of loading it in open wagons and carts, frequently across the sidewalks, and hauling it through the streets. The ordinance takes effect May 15th. In the matter of sewers, school hygiene, slaughter-houses, and gas-houses the association has accomplished much, and hopes in another year to have in operation public crematories for consuming refuse.

Leprosy in New Caledonia.—Paris papers state on good authority that leprosy is spreading in New-Caledonia in a most alarming manner. Of 40,000 Kanakas no fewer than 5,000 are described as suffering from the terrible disease. Till quite recently the public authorities had taken no measures to prevent it from spreading; but now two subordinate colonies have been created.

A Bill to Incorporate a Missionary Medical College in New York City has passed the State Senate, and seems likely to get through the Assembly. The bill provides for the creation of an institution which shall grant medical diplomas on condition that the persons using them practise out of this country. There is no evidence that the proposed medical institution can and will give thorough medical instruction, and it looks very much like a diploma-mill floating a gospel banner. If medicine is to help the missionary cause it can only be through physicians well qualified in their calling, and the proposal to establish a new medical college which shall take clergymen and make cheap doctors of them seems most unwise in every way. We trust that the bill will be killed. We have already ample opportunities for medical instruction in this city.

The Game for Medical Students.—A writer in the *Medical Press* who is both a doctor and a foot-ball player says: The game of foot-ball is *par excellence* the game of medical students, as is evinced by the numbers of these that obtain places on good teams in all medical teaching centres, the reason that it is so to my mind is two-fold, (1) it is played in the winter time, when the medical schools do most work, and (2) in foot-ball they get the maximum amount of exercise with the minimum expenditure of time—healthy exercise which is absolutely necessary to enable them to attain to the "mens sana in corpore sano."

Physicians' Books of Account are "Privileged."—A local court has decided that a debtor who is a physician cannot be compelled to deliver up his books of account to his receiver, who has been appointed in proceedings supplemental to execution. By the order appointing the receiver the latter acquired title to the accounts but not to the books as well. "In the complicated affairs and relations of life the counsel and assistance of clergymen, physicians, and lawyers often become necessary, and to obtain them men and women are frequently forced to make disclosures which their welfare and sometimes their lives make it necessary to be kept secret. Hence, for the benefit and protection of the confessor, patient, or client, the law places the seal of secrecy upon all communications made to those holding confidential relations, and the courts are prohibited from compelling a disclosure of such secrets. The safety of society demands the enforcement of this rule." For this reason it is held that the physician's account books, containing information which would be privileged as concerns his patients, are not subject to discovery and inspection in an action between the physician and a third person.—*N. Y. Medical Journal.*

Pneumonia as it Prevailed during Epidemic Influenza.—Statistices of pneumonia as it prevailed during the recent epidemic influenza in Philadelphia, Boston, and New York were given by Drs. Pepper, Shattuck, and Janeway, in papers read before the New York Academy of Medicine, April 16th. Those from Philadelphia were based on reports from two hundred and seventy-two physicians in private practice; those from Boston and New York on the records of public hospitals, and of the Bureau of Vital Statistics. There was not that predominance of the catarrhal over the croupous form which some had supposed to exist; the number of cases of both kinds was about three times as great as for the same period in preceding years; the mortality rate was not greater; the cerebral symptoms were unusually severe; marked mental depression was common; high initial temperature was the rule; the pleurisy was usually plastic; in Philadelphia pericarditis was frequent, and jaundice was present in a considerable proportion of cases; there was apt to be gastric disturbance and diarrhœa; in New York children with influenza were affected with pneumonia less frequently than adults; the lesions were the ordinary ones of catarrhal and croupous pneumonia. Few bacteriological studies had been made, and these showed the pneumococcus of Friedlander while the streptococcus was absent.

Public Lectures on Nursing and Hygiene.—The Montgomery County (Pa.) Medical Society has instituted a course of lectures on nursing and hygiene for the laity. The fifth lecture of the course, on "surgical dressings and bandaging," was delivered in Norristown on April 9th, by Dr. Alice Bennett, President of the Society.

St. Louis has still Another College.—The medical faculty quarrel in St. Louis has resulted in the establishment of a new college, to be called the Marion-Sims Medical College. The projectors of the new institution are to build at once, and propose to be ready for students in the fall.

Hydrophobia in Boston.—Dr. Harold C. Ernst, recently read a paper before the Suffolk District Medical Society on the subject of rabies, in which he affirmed that the disease was epidemic in Boston and its vicinity.

Guarding against Contagion in Cattle.—Dr. Armstrong, United States Inspector of Live Stock, is on a tour of inspection, taking in the stock yards of various cities in the West. He is under instructions to see that separate pens are provided for cattle that have been subjected to danger of disease, and that for cars in which they are carried to the yards a system of immediate and thorough cleansing is adopted.

Norway, which has a population of 2,000,000 souls, is divided into 152 medical districts, with 581 doctors and 89 druggists' shops.

Liabilities for Injurious Patent Medicines.—The Supreme Court of Georgia has just rendered a decision, says the *New York Herald*, which is likely to attract widespread attention, and to have a salutary effect on the preparation of patent medicines. It holds that the proprietor of such a preparation is liable to damages for injury done to any person who takes the medicine according to directions. This liability does not fall upon the druggist who sells the medicine, but upon the proprietor, even when the consumer buys not from him directly, but from the druggist.

An Investigation of the Use of Electricity in Uterine Fibromata.—The Philadelphia County Medical Society has appointed a committee, consisting of Drs. Parvin, Hirst, Montgomery, Massey, and Baldy, to conduct a series of observations relative to the effect of electricity in fibroid tumors of the uterus.

Adirondack Sanitarium.—The results of the "cottage plan" of the treatment of phthisis pursued at the Adirondack Sanitarium, at Saranac Lake, New York, as shown in their last report, are as follows: Of the 96 patients under treatment during the past nine months, 1 died, 11 who continued to lose ground were returned to their homes, 17 have somewhat improved, a similar number have been restored to lives of usefulness, and 8 are thoroughly cured. The patients now under treatment number 42. The financial condition of the institution continues very satisfactory.

An American Merchant's Bequest.—An old New York merchant, Mr. Thomas Hope, has bequeathed to his native town of Langholm, Scotland, the sum of $400,000, to found a hospital and dispensary. Langholm has a population of about four thousand.

The Medical Editors' Association will meet in annual session on the evening of May 19th, in the lecture room of the dental department of Vanderbilt University, Nashville.

Chloroform v. Ether in Paris.—Owing to a recent chloroform accident in Paris, the Director of Public Assistance caused a report to be made on the surgical operations which have been performed during the last ten years in the hospitals of Paris. As a result of this report, it appears that the accidents due to the employment of chloroform have been in the proportion of 1 in 1,236; those due to ether have been only 1 in 12,581 cases.

A Doctors' Home.—The Alabama State Medical Society has under consideration a project to build a doctors' home, and the county associations of Jefferson, Montgomery, and Mobile have given it their approval. The plan looks to no great immediate results, but has an eye to the future. Under it each member of the county societies is requested to contribute annually the sum of one dollar, and when a sufficient fund has been raised, a building will be provided and arrangements made for receiving inmates.

An Old Practitioner.—Dr. James Kitchen, of Philadelphia, now in his ninetieth year, has been sixty-eight years in the practice of his profession.

An Attempt to Remedy the Dispensary Abuse.—At a recent meeting of the Executive Committee of the Eye, Ear, Nose, and Throat Free Hospital, of New Orleans, the following preamble and resolution were adopted unanimously: "*Whereas*, It is our imperative duty to husband our resources, in order the more effectually to relieve the truly poor and needy; and whereas our experience makes it evident that persons fully able to pay for medical services have, with the evident intention of avoiding the expense of the employment of a physician, applied to the free hospital for and obtained gratuitous treatment; and whereas, by encouraging such practice, we are not only violating the trust confided to us, but also doing a great injustice to the medical profession, a class of meritorious citizens noted for their liberality and charity; therefore,

"*Resolved*, That a committee of two be appointed, with instructions to confer with similar committees from other charitable institutions, and also from the Parish Medical Association, in order to study this question, and devise such means as in their judgment can be adopted to remedy or minimize the abuse."

Colles's Law.—One of the most important of all pathological facts is the transmission of syphilis from father to child without infection of the mother. Many men aware of this fact, and already victims of syphilis, hesitate to marry, almost entirely on account of their future offspring rather than their future wives. The extinction of the syphilitic virus in well-fed patients is one reason why the disease is not often seen in its hereditary form in children among the prosperous classes of society, as Paget has had occasion to observe. The immunity of the mother is a question which deserves the closest investigation. According to a well-known law, first laid down by Colles and afterward confirmed by Baumès, a mother who suckles her syphilitic child never thereby acquires syphilis. Diday, Jonathan Hutchinson, and others have established this law; and the exceptions are so few as almost to prove the rule, if not themselves "suspect." Dr. L. Merz has published notes of two exceptions in the *Archives de Toxicologie* for January. — *British Medical Journal.*

Cooperstown Hospital.—An unknown benefactor has sent $10,000, with which to help erect a hospital at Cooperstown. The donor suggests as a name "God's Providence Hospital." This we submit might be appropriate but it would be very awkward.

Medicine in May.—In the rainy month of April, eleven State medical societies held their annual meetings. These were mostly the societies of the Southern States. In the coming merry month of May medical talent aggregates in more northerly sections, and twelve societies will meet as follows: Illinois, Chicago, May 6th; Kansas, Salina, May 13th; Louisiana, Baton Rouge, May 13th; Nebraska, Beatrice, May 13th; Arkansas, Little Rock, May 14th; Indiana, Indianapolis, May 14th; Kentucky, Henderson, May 14th; Washington, Spokane Falls, May 14th; Michigan, Grand Rapids, May 20th; Missouri, Excelsior Springs, May 20th; North Carolina, Oxford, May 27th; Connecticut, New Haven, May 28th. Besides these, the Association of American Physicians, and the Association of American Surgeons meet in Washington, D. C., May 13th, 14th, and 15th.

The Alabama Dental Association held its annual meeting in Birmingham on April 8th.

Changing the Name of a Hospital.—Mr. Charles Parsons, of St. Louis, has offered $20,000 to the board of directors of the Augusta Free Hospital of that city, on condition that the name be changed to The Martha Parsons Hospital for Children, in memory of his deceased wife.

The Northwestern Wisconsin Medical Association, at its quarterly meeting in Oshkosh, on April 8th, elected the following named officers: *President*, Dr. Steele, Oshkosh; *Vice-President*, Dr. Pelton, Waupaca; *Secretary and Treasurer*, Dr. Simonson, Pittsville; *Censor*, Dr. Oviatt, Clintonville.

Death of St. Louis' Leper.—James Brennan, a leper, who made considerable stir in St Louis some time ago, is dead. He was seen by several physicians, and his disease was diagnosed as leprosy. He was quarantined by the Board of Health, but escaped about a year ago, and it was several days before he was secured by the health officers and sent back to Quarantine Hospital. It was after this his sister, aided by several physicians, instituted proceedings to secure his liberty. He was brought up to the City Hall and examined by a number of experts, and the consensus of opinion sustained the Health Department. He was then brought into the Circuit Court on a writ of habeas corpus, but this plan also proved a failure, and since then he has remained in the hospital, thirteen miles below the city.

A Physician Sues a County.—Dr. M. Rockman, coroner of Lewis and Clarke County, Mont., has brought suit against the county for his fees for inquests made during the past three months, and which the authorities refused to pay.

Color Blindness among Sailing Captains.—Dr. B. Joy Jeffries lectured before the Massachusetts Yacht Club, in Boston, on April 11th, on the report of the International Maritime Conference on the danger and control of defective vision and color blindness. The conference, representing twenty-six nations, had agreed that the dangers from color blindness had not been overstated, and that there was need of standard requirements for detecting it. The conference wisely recommended no change in the form and color of lights used at sea, but had decided that those in use at present must be recognized, and it strongly urged that the officers of all vessels, instead of only steamers as at present, be subject to inspection by a competent board established by act of Congress.

Resection of the Lung.—This operation was performed before the members of the German Surgical Congress in Berlin, on April 11th, for the removal of a tuberculous deposit. At last accounts the patient was still alive.

A Reference Medical Library in Chicago.—The medical profession of Chicago has at last the prospect of access to an excellent reference medical library. The trustees of the Newberry library have decided to include this as a department of the library, and to that end have solicited the aid of several prominent physicians in the selection of books and periodicals. The Chicago Medical Society has wisely decided to transfer its own nucleus of a library to the Newberry trustees.

The Florida Medical Association held its annual meeting in Ocala on April 8th, 9th, and 10th.

Chicago Policlinic.—At the recent special course in abdominal and pelvic surgery at the Chicago Policlinic, one hundred and twenty-seven practitioners from the Northwest were in attendance. At their unanimous request, a similar course will be presented next winter. Dr. N. Senn and Dr. Chr. Fenger have been elected regular professors of surgery in the Chicago Policlinic.

Alumni of Mount Sinai Hospital, New York.—All physicians who have served a term on the staff of the Mount Sinai Hospital, New York, and who have not been reached by mail, will please send their names and addresses to Associate Alumni, Mount Sinai Hospital, Sixty-sixth Street and Lexington Avenue, New York City.

A Medical Man for President of Board of Health.—At a stated meeting of the New York County Medical Association, held April 21, 1890, the following resolution was unanimously adopted:

Resolved, That the New York County Medical Association earnestly and respectfully urge the members of the Legislature, now in session, to give their influence and votes for the passage of the Bill now before the House, having for its object the repeal of the law by which a physician is made ineligible for the position of President of the Board of Health of New York City.

Closing a Hospital for lack of Funds.—There is danger that the City Hospital in Oswego, N. Y., will be closed by reason of the failure of the City Council to come to its support. The annual expense is only about $4,500, and the council is asked to contribute $1,000 of this, the balance being made up from the proceeds of fairs and by private contributions.

Contagion by Kissing a Corpse.—A woman in Ohio recently lost her child by diphtheria, and forced her other children to kiss the dead body. The latter also sickened and died.

"**La Rivista Medica**" is the name of a new bi-monthly medical journal published in Malta. Drs. Borg and Zammit are the editors of the journal.

An International Atlas of Rare Skin Diseases.—Unna, of Hamburg, writes in his *Monatshefte für Praktische Dermatologie* that he intends to publish, with the assistance of Duhring, of Philadelphia, Leloir, of Lille, and Malcolm Morris, of London, an atlas of skin diseases, the peculiarity of which will consist in the fact that only very rare and unusual diseases will be pictured and described. It is to be published in yearly parts in English, French, and German. Why not in Latin only?

Hypnal is the name of a new compound introduced into medicine by M. Bonnet, of Paris. It is made by uniting antipyrin and chloral, and its chemical name is said to be trichloracetyldimethylphenyl. It is given internally in doses of fifteen grains and is said to be not unpleasant to take, and to have some hypnotic power.

Dr. Destot, of France, has succeeded in inoculating himself with psoriasis by the insertion of scales into the skin of the shoulder. Dr. Destot's feeling of scientific triumph ought to be tempered with some sensations of dismay. We hope the doctor will crown his achievement by curing his case.

Trichinosis.—Thirty cases of trichinosis have been reported to the health authorities in Aurora, Ill. Some of the cases are stated to have come from eating imported sausages, while others have been traced to the native hog.

Dr. Hiram B. Tibbetts died in Concord, N. H., on April 8th, at the age of seventy-eight years. He was a graduate of the Harvard Medical School, and practised medicine years ago in Natchez, Miss. He afterward engaged in cotton planting in Louisiana. At the close of the war he returned to Concord, where he has since resided.

The Botkin Hospital Gazette is the English name of a new weekly medical journal to be published in St. Petersburg. The editor of the new journal is Dr. N. P. Wassilieff.

Is it Virginia's First Woman Physician?—The State Board of Medical Examiners, whose session in Richmond has just closed, had for the first time among the applicants for the privilege of practising medicine in Virginia, so says the *Baltimore American*, a woman, Miss C. L. Haynes, who was recently elected assistant physician in the Western Lunatic Asylum. Miss Haynes passed a successful examination, and was awarded a diploma to practise her profession in the State.

A Registration Bill in Massachusetts.—The legislature of Massachusetts has under consideration a bill providing for the registration of practising physicians. "A record shall be kept of all persons registered and certificates issued, and any person not registered who shall use or advertise or in any way permit the title of doctor or doctor of medicine to be used in connection with his name, or shall do any act which may operate to lead any person to believe or infer that he or she is entitled to the use of such title, shall be punished by a fine not exceeding $500, or imprisonment not exceeding two years, or both fine and imprisonment." The passage of the act is opposed by some women representing the "constitutional liberty league," though it is hard to say on what grounds.

Dr. Rufus McCarthy, surgeon on the United States man-of-war Yantic, died of pneumonia aboard that ship at Key West on Saturday afternoon, after a four days' illness. He was twenty-eight years old and born in Detroit.

Dr. George Thurber, one of the best known botanists in the country, died recently at his home in Passaic, N. J.

A Singular Complaint against Two Surgeons.—The Minnesota State Medical Board was called together recently to consider a singular case. A resident of St. Paul preferred charges against two surgeons of that city. He asserts that he was recently having a leg operated on, in the course of which he was given chloroform. When recovering from the effects of the anæsthetic he unconsciously thrashed his arms about and struck one of the doctors in the face. The physician lost his temper, and savagely struck the semi-conscious man, knocking out an eye. It is claimed in defence that the injury was purely accidental, and occurred while the surgeons were holding the man down to prevent him from injuring himself. This is the first time that the Board ever sat as a Medical Court.

Neglect to Report Contagious Diseases.—The Commissioner of Health of Chicago complains that the physicians in that city do not comply with the law in regard to reporting contagious cases which come under their notice in the course of their professional duties. This negligence, he says, causes serious danger to the public health and impedes the working of the department. In future he threatens to prosecute every offender under this head, and have the maximum penalty of $200 enforced.

A Doctors' Building.—A stock company is said to have been formed in Pittsburg, the members of which are all physicians, for the purpose of erecting a ten-story building on Penn avenue, to be occupied by physicians only, who will have their offices there. There will be two elevators in the building, so that patients will have no trouble in reaching the upper floors. The ground floor will be rented out for storerooms.

Educating Colored Physicians.—The first annual session of the medical department of the New Orleans University closed on April 4th. The department has been established for the education of colored physicians.

Tulane University.—The Commencement exercises of the medical department of Tulane University, New Orleans, were held in that city on April 1st. There were ninety-three graduates.

A Woman's Will.—A will was recently admitted to probate in Philadelphia which was written in lead pencil on the back of a physician's prescription. The testatrix was a Mrs. Beresford.

A Missing Diploma.—Dr. Alfred V. Forgey, of this city, writes that he has lost his diploma, issued by the Medical College of Ohio in 1873, and two pharmaceutical certificates. He believes that they were stolen, and thinks that some one may attempt to practise on the strength of them.

The Kent County (Mich.) Medical and Surgical Society was recently organized in Grand Rapids, by the physicians residing in that city. The Society has obtained a charter from the State, and a meeting will soon be held for the election of officers.

The Trials of St. Louis Physicians.—There must be something wrong with St. Louis air, for the medical profession in that city is by no means a harmonious body. Seven of the faculty of the St. Louis College of Physicians and Surgeons have recently resigned, the resignations, it is said, having been brought about by an amendment to the constitution, of recent adoption, which placed the chairs of the retiring professors entirely at the disposal of the Dean of the College and the Board of Trustees. Only four members of the faculty have a vote in the Board of Trustees, and these four, with the concurrence of the remainder of the Board of Trustees, who are all laymen, can depose any of the other professors of the institution at pleasure. The laymen have been in the habit of letting the physicians in the Board of Trustees have their own way in the entire management of the institution. Hence, these four gentlemen could at pleasure depose any of their fellow-professors. That is what the fellow-professors objected to, and that is why, so the report runs, they resigned. There are rumors, also, of disagreement among other medical associations in that city.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, March 7, 1890.

(Continued from page 454.)

FRANCIS P. KINNICUTT, M.D., PRESIDENT, IN THE CHAIR.

Is Excision of the Appendix Vermiformis Justifiable in Cases of Recurring Appendicitis?—DR. W. T. BULL made the following remarks in introducing the subject for discussion:

It is not my purpose to suggest for discussion the general treatment of appendicitis and its accompanying accidents, peritonitis and perityphlitis. We have had this subject before us frequently, and I believe are in favor of early operative treatment when symptoms of urgency are present.

In the absence of urgent symptoms, or in the presence of an inflammation limited strictly to the appendix (as shown by clinical evidence), it has generally been held that medical treatment was all that was called for. But I do wish to acquire information from your experience and reading, that may help decide the question of the propriety of surgical interference. When the appendicitis recurs, should the organ at fault be removed?

The fact that recurrence is frequent is well known, but we lack exact data. The largest percentage of such observations has been noted by Kraft[1] (of Lausanne), who found that twenty-six of one hundred and six patients with perityphlitis had had previous attacks not accompanied with suppuration. Fitz and Pepper have both stated that recurrence is frequent, and Lee and Murphy (whose paper I have seen only in abstract) state that their observations concide with Kraft's. All of us have met with patients who have had several attacks at varying intervals. In the last one I encountered the interval had been twenty years. It may, therefore, be considered proven that one attack of appendicitis may lead to another, and even to frequent repetitions, and that some of these attacks may lead to suppuration, or perforation, and the accidents above mentioned. Assuming that recurrence is the probable outcome of one attack, we lack information as to the cause of the recurrence. If merely uncomplicated appendicitis, it may recover as before.

If the secondary inflammation occurs, it may recover spontaneously, or by proper surgical management, in the majority of cases.

In the application of any surgical operation to the cure of disease, we should consider the danger to life from the condition which it seeks to relieve, and contrast it with the risk to life from the operation. If the disease be threatening life, a dangerous operation is proper. If it merely interfere with the comfort or the safety of the patient, only an operation of moderate risk can be recommended. A patient who has one attack of appendicitis, is, in my opinion, not a proper subject for operative treatment. Recovery is probable with simpler and safer methods of treatment. He has as much right to expect immunity from another attack as a recurrence, and in the latter event an equal chance of favorable or unfavorable result. The danger to life is trifling, and needs no protection from such an operation as removal of the appendix. But the subject of frequent recurrences, with the constant suspense and dread in the intervals of another attack, with the frequent interruptions to business, or labor, or even pleasure, may properly undergo surgical treatment which is not attended with great risk. While I should not, in the light of present experience, encourage operations for one attack of appendicitis without urgent symptoms, I am unqualifiedly in favor of them when the attacks frequently recur.

[1] Lee & Murphy, Medical News, December 28, 1889.

Is the operation easy and safe? And does our experience at the present time justify such statements as the following, which have been advanced?

Morton[1] speaks of it as "Comparatively trivial operation at a time and under conditions when prompt and permanent relief and recovery can almost invariably be secured." And Senn[2] writes: "Excision of the appendix in cases of simple uncomplicated appendicitis is one of the easiest and safest of all intra-abdominal operations."

On the other hand, in one of the cases operated on by Mr. Noyes,[3] the appendix and cæcum were buried in adhesions, and the dissection was complicated and tedious.

In a case under the care of Dr. J. C. Lester, of Brooklyn, operated on by myself last winter, the attacks had recurred with considerable regularity at intervals of three weeks for four months. They lasted only two or three days and were always accompanied with fever. The patient was a lady, aged sixty-three years, and of good health excepting this condition. A small ileo-cæcal tumor could be felt. On making an incision which opened the peritoneal cavity and also explored the iliac fossa, the condition was as described in Mr. Noyes's case. To dissect the appendix from this mass of plastic exudation would have been a prolonged operation, difficult and risky on account of the extensive raw surfaces which would be left behind in the peritoneal cavity. I closed the peritoneal wound and left a drain in the wound outside the cavity. There has been a marked improvement in her condition, there is a constant but purulent discharge, trifling in quantity, from the tube, and anything like a repetition of the attack has occurred only when the tube was occluded, or temporarily dispensed with. She and her family decline the risk of further operation. In a case already reported where I did laparotomy expecting to find an abscess, I met with a similar embedding of the appendix alone (the cæcum was free) in such a firm mass of exudation that I deemed it prudent not to attempt its excision.

In another patient, a boy of fourteen, who had experienced a number of attacks in one year, I recommended excision of the appendix, which was done later by one of the most competent and experienced surgeons in the city. The mass of fibrinous exudation about the cæcum and appendix was so large that a stricture of the cæcum was diagnosticated, an anastomosis made between the lower end of the ileum and the ascending or transverse colon. By the time the wound of this operation was healed, the attacks recurred. A subsequent operation, at which I was present, was done with great skill and patience, and the appendix found containing a small amount of mucopus, and a concretion in the midst of the exudation. But it was a very difficult performance, and one by no means devoid of risk, but fortunately followed by recovery and no return of symptoms. These are different conditions from those met with in the cases reported by Senn, and justify the conclusion I have formed, that excision of the appendix is not to be considered an easy and safe operation. While it may, on technical grounds, be considered less dangerous than other intra-abdominal operations, where the mortality rate is small, such as craniotomy in uncomplicated cases, removal of the uterine appendages, we are liable to meet with conditions, the management of which makes the procedure risky to the life of the patient—and I may add, that at present I know of no symptoms, or signs, or method of examination by which we can detect these conditions.

In the boy above mentioned upon whom two operations were done, the most careful palpation did not reveal the presence of such exudation as was discovered on dissection. In the presence of a distinct induration or tumor I should certainly think the operation complicated and dangerous, while admitting, that, if the appendix

[1] In a paper read before the College of Physicians of Philadelphia, January 1, 1890.
[2] Journal of the American Medical Association, November 2, 1889.
[3] Tiern & Swallow, Lancet, February 9, 1889.

were free or provided with light and recent adhesions, its removal would be a simple, reasonably safe procedure. The testimony of statistics we cannot yet give, for few operations have been done. But the number is increasing, and we shall soon be in a position to make sound conclusions. It is to be hoped, however, that operators in reporting cases, will ascertain whether hernia has followed the extensive incision of the abdominal wall, which has been practised "at least three," and even four and five inches in length. I have seen this winter half a dozen cases of serious ventral hernia following operations on the appendix, the victims of which complained bitterly of their condition. This sequel threatens to interfere with the usefulness, and disturb the comfort of a certain number of patients whose lives have already been risked by the operation, unless we believe that operation to be absolutely safe. With this additional uncertainty attached to the fate of the patient, and with the traditional uncertainty of the course of the disease, it is of the greatest importance that we bring every accessible fact to light that can help us to formulate a safe rule of treatment.

Analogy Between Operations for Appendicitis and for Salpingitis.—Dr. W. M. Polk said the subject discussed in the paper was one to which he had given some attention in connection with his gynecological work. It had seemed to him that in many respects the question of operating for appendicitis was in about the same stage as was that of operating for disease of the uterine appendages several years ago. The removal of the uterine appendages which had no adhesions was quickly found to be, under antiseptic peritoneal surgery, one of the simplest operations, and was very rarely attended by a fatal result. He supposed that was about the position which Dr. Bull would grant with regard to removal of the free vermiform appendix. But when it came to removal of the tubes and ovaries which were extensively adherent and matted together with the pelvic contents in general, as they frequently were, it was found that a different method had to be resorted to. In the earlier operations it was considered necessary to bring the site of the diseased organs into view, which resulted in a good deal of exposure of the abdominal contents. But after a time it was discovered that the diseased mass could be separated from its attachments—literally torn out—by mere touch, without the aid of vision, and that the resultant hemorrhage, which at first had been looked upon as a great drawback to proceeding in this way, really amounted to little, and had no material influence in the production of sepsis, either immediate or remote. The cases with adhesions, therefore, came to be operated upon as freely as others, and the immediate results, with rare exceptions, had been as favorable as those following operations on cases in which there were no adhesions. It was true that in these cases one was operating in a region in which the vessels were much less important than he was likely to come in contact with in appendicitis, for while all knew that the appendix frequently lay close to Poupart's ligament, yet it not infrequently lay alongside the larger vessels, might even cross them and lie down in the pelvis, so that any effort at tearing up the adhesions except by careful dissection seemed to him, independently of the nature of the organ one was dealing with, to be attended by somewhat more risk than the same procedure addressed to the tubes and ovaries. If the tube and ovary were torn there would merely be an escape of pus, which could easily be washed out and the diseased mass entirely removed. If one happened to tear the attachment of the stump to the uterus, the bleeding would be of little consequence, and could be readily corrected; but if one tore the attachment of the vermiform appendix to the intestine, or tore the intestine itself, another operation would be added to the original one which required a good deal of time and skill. He thought, therefore, that a little greater conservatism was proper in dealing with cases of appendicitis than in dealing with cases of diseased tubes and ovaries. It would be interesting in this connection to know what was the danger to life from recurrent attacks of appendicitis, and he asked Dr. Bull what was the likelihood of internal perforation.

Dr. Bull replied that he knew of no statistics bearing on this question.

Dr. Polk thought the answer to this question would have an important bearing upon the course of treatment in recurrent appendicitis. When one saw a case for the first time, he was brought face to face with the question of likelihood of perforation taking place at some time into the abdominal cavity. If the history of cases of recurrent appendicitis were at all like that of cases of ovaritis and salpingitis, it would seem to show a tendency in the vast majority of instances to the development of abscess which pointed outward. The adhesions which formed around the extravasated material, or escaped intestinal contents, would shut them off, and at each successive attack further exudation would add thickness to the capsule shutting off the inflammatory mass from the peritoneal cavity.

Would Make Exploratory Incision.—He believed an exploratory incision was always advisable. That was the rule generally adopted with regard to inflammation of the uterine appendages. It was no longer regarded necessary, in starting out with laparotomy, always to remove the offending structure. The surgeon now considered himself entirely free to deal with the case according to the conditions which he found on entering the abdomen.

From a Medical Point of View.—Dr. Beverley Robinson said that his discussion of the subject would be from a medical, not a surgical, point of view. With this explanation, it would be understood that in the cases which he had regarded as those of appendicitis, the diagnosis had rested on the symptoms. So far as recurrent attacks of appendicitis in hospital practice were concerned, he confessed not to have encountered them. Within the past three or four years he had seen two cases which he had regarded as of this nature, in private practice. One case occurred in a boy of about twelve years, the attacks seeming to follow some error in diet. There was pain in the region of the cæcum, some resistance on palpation in the same locality, there was either nausea or slight vomiting, and, he believed, also constipation. He saw the boy in two attacks, and the symptoms were relieved within a few days by what seemed to him to be rational medicinal treatment, namely, quiet, milk diet, small doses of opiates, enemata, and, perhaps, a commencing laxative dose of calomel. The boy recovered each time without it being considered necessary to resort to surgical interference.

The past week he had witnessed another attack in a boy, eighteen or twenty years of age, whom he had first treated for the same condition last summer, at Newport. One evening, in passing the house of Dr. Bull, he thought of going in and asking him to make an exploratory incision in this case, but on the following day he found the young man much better. In view, however, of the serious symptoms present during the last attack, which had given him a good deal of solicitude for a period of forty-eight hours, he thought that if there should be another recurrence he would have an exploratory incision made. If the appendix could be easily reached, were non-adherent, and could be removed without risk to life, it seemed to him at first thought that it were better taken away. In the second case related, however, the judgment of the surgeon could be relied upon as to further procedure after opening the abdomen.

Let Experience Answer.—Dr. Peabody thought the various questions propounded in the paper could be answered only by surgical experience. For example, the question whether the operation is dangerous or not? The reply to one of the interrogatories, however, must come as much from the physician as from the surgeon, namely, should the operation be done for frequent recurrences of appendicitis? The physician must learn from the surgeon how grave was the operation, but he could himself decide

as well of the necessity of an operation as indicated by the incommoding of the patient, by frequently recurring attacks, and by the danger of a recurrence at a time when surgical aid could not be reached if it were demanded. These two reasons for surgical interference, he thought, were in fact sufficient in many cases to justify resort to it when the appendicitis recurred at frequent intervals. As the other speakers had said, the form of operation seemingly indicated at the time was the one which should be done.

Recovery from Recurring Appendicitis Usual.—Dr. W. H. Draper said he had seen a number of cases of recurring appendicitis, at least cases which he had supposed to be such, in which recovery had taken place without an operation. He did not recall a case of fatal peritonitis from appendicitis where there had been a previous attack. It would be very interesting to know the experience of the profession with regard to the number of fatal cases in which there had been previous attacks. As stated, in his experience the fatal cases had been in persons who had never before had an attack.

How many Recurrences Indicate an Operation?—Dr. Robinson inquired how many times there must be a recurrence to justify interference; two, three, or four times? Or did it depend on the severity of the attack?

Dr. Clement Cleveland had seen several cases of appendicitis, but all had recovered under operative treatment (at the first attack), and the histories offered no answer to Dr. Bull's question. He had been much interested in what Dr. Polk had to say in comparing operations on adherent Fallopian tubes and adherent vermiform appendices, and had been much impressed with Dr. Bull's conservatism in breaking up the adhesions in the latter-named cases. It was an entirely different matter where we had the tubes and ovaries embedded in the pelvis. At present we took them out and the patients recovered even under the most extreme circumstances. But now and then, when the intestines were attached firmly to the tubes, it became necessary to observe the utmost caution in tearing them away. He had himself lately seen two such cases. In one he operated himself for pelvic hematocele, the patient being already in a septic condition. He found the intestine firmly adherent to the mass, and while dissecting it away, which he thought could be done easily, his finger entered the pus-cavity. He could then do no more than wash out the pus-cavity, pack it with gauze (it was situated near the abdominal wound), and put in a drainage-tube. The patient died within forty-eight hours. The point of interest in the case, as it related to this discussion, was the fact that thirty-six hours after the operation a fecal fistula became evident, and at the post-mortem examination it was found that the intestine had broken down at the point where it had been adherent to the mass. Evidently the abscess was pointing in that direction and would have opened into the intestine, had he not disturbed it. Judging from this case and others which he had seen, tearing away tubes and ovaries from their adhesions in the pelvis was entirely different from tearing up adhesions about the vermiform appendix.

Six Cases of Appendicitis; Three Operated upon, All Died; Three not Operated upon, All Recovered.—Dr. Andrew H. Smith recalled six cases of appendicitis with suppuration which had come under his observation, in three of which surgeons operated and all died, while the other three not operated upon recovered. Of the six only one was a case of recurring appendicitis. It was operated upon at the second attack, and pus was reached almost immediately upon division of the abdominal walls. The search for the appendix, however, was prolonged, the intestines protruded from the wound, and the patient never rallied from the ether, although in fairly good condition before the operation. In one of the other fatal cases the appendix was found and removed; in the other the abscess was opened and no attempt was made to find the appendix. In one of the cases not operated upon the pus discharged into the bowel, and recovery took place; in the other two the pus found its way to the surface.

Do Recurrences Make a Firmer Barrier?—He thought every recurrence of an appendicitis must result in a firmer barrier to resist rupture of the abscess into the peritoneum, if one had formed, rendering more likely its pointing externally or into the cæcum. In recurrent attacks it seemed that no pus formed, or else it was small in amount and escaped into the bowel and out with the fæces, without detection. He would be loath indeed to sanction an operation in these cases as a mode of prophylaxis. His experience in that direction had not been at all satisfactory.

Three Conditions of Appendicitis.—Dr. George F. Shrady said, we must take into consideration that there were three conditions of appendicitis. One was simple inflammation, which left no results, or only slight adhesions. Another terminated in fibrinous effusion, more or less extensive; while the third terminated in abscess.

With reference to the first condition, he had had a good deal to do with one case of the kind which made a great impression upon him. A physician whom all present had known, had had four distinct attacks of appendicitis, in all of which the question of operation arose. Dr. Shrady had seen the patient in three of the attacks, all of which were well pronounced, while the fourth occurred in Paris, where the patient was seen by a distinguished surgeon, who made a like diagnosis. There also the question of an operation came up. Each attack was attended with all the usual severe symptoms which would appear to usher in the formation of an abscess; there was dulness, tenderness, more or less rigidity, and some œdema in the neighborhood of the cæcum. In each attack the advisability of operation was freely discussed. The patient was willing to take the risks, but in each instance the symptoms gradually disappeared, and he recovered. He asked the speaker, should he survive him, to examine his appendix, which was done when death occurred some time subsequently, of another cause. The appendix was found perfectly sound. There was not the slightest appearance of any inflammation around it; it was not even thickened.

Usually, in cases which were acute and terminated in abscess, an operation was required at once, and generally resulted in cure. He had himself operated several times for abscess with a good result. Three or four times, however, he had observed all the symptoms pointing to an abscess except well pronounced fluctuation through the abdominal walls, yet on introducing the hypodermic needle the tap proved dry. He had seen two or three distinguished surgeons do the same thing.

He quite agreed with what Dr. Smith had said, that frequent attacks of fibrinous inflammation were so many guarantees against further trouble. Given a case in which there was a suspicion of progressing disease in the appendix, it seemed to him we were entirely warranted in making an exploratory operation; but after having been satisfied that the disease was not progressive, that the adhesions were firm, he believed we ran great risk in going farther. It should be remembered, also, that there was sometimes great difficulty in making a diagnosis in these cases. In the case of the physician just mentioned, he had studied it with great interest, and the physician himself, who was distinguished for diagnostic acumen, had studied it with him, and believed on two occasions that pus had formed, and the operation was postponed because no pus was found on hypodermic puncture.

He recalled one case near his country home, in which he discovered fluctuation and other evidences of pus formation, and prepared to operate, but on the morning of the day when the operation was to have taken place, the abscess emptied spontaneously into the cæcum.

Altogether each case depended upon its own merits, and the question of treatment rested upon the judgment of both surgeon and physician. We had to wait for statistics, and in the meantime the limits of the operation must be considered *sub judice*.

Dr. E. L. Partridge said there was one class of cases to which comparatively little attention seemed yet to have been given. They were those which Dr. Shrady probably had in mind, in which the appendix alone was affected, with little or no peritoneal adhesive inflammation. The symptoms, it would seem, must be vague, and it was difficult to fully convince oneself of the accuracy of the diagnosis, yet post-mortem examinations had shown that such cases did occur. Operations would come to be performed, he thought, in cases in which the appendix would be found distended, containing perhaps a good deal of pus, perhaps only a little, the cases giving a history of recurrent pain, showing that considerable time had been occupied in the production of the pathological changes; yet very little surrounding peritoneal inflammation or adhesion would be found to have taken place. He would suppose that these cases, when recurrent, were very highly dangerous, and did not belong to the class referred to by Dr. Draper and others, in which recurrence afforded protection by throwing out further exudate. Where there were repeated attacks of local pain, pointing to appendicitis, but absence of induration, he would suppose the prognosis was grave.

The President said he supposed Dr. Partridge referred to cases in which there had been an inflammation of the appendix, but which had entirely subsided when another attack occurred, not dependent upon the first.

Dr. Partridge replied that there might have been a catarrhal condition, or small ulcer, or fecal matter left in the appendix, leading to the second attack, or, seemingly, there may have been no remains of the previous attack whatever.

Dr. Shrady remarked that the cases referred to by Dr. Partridge were precisely those which called for an operation and removal of the appendix.

The President thought further experience was necessary to determine whether the mortality attending recurrent attacks compared favorably or unfavorably with that attending the first attack. He had himself seen one case in which there had been three attacks, the diagnosis apparently being beyond question. The patient had now been free from a recurrence for five years. In two other cases the recurrent attacks passed off with comparatively light symptoms. In a case which entered his ward at St. Luke's Hospital, the first attack had been diagnosticated as appendicitis, in the second the same diagnosis was made, but by different physicians, and in the third attack an immediate operation was deemed necessary; but the symptoms rapidly improved, and within twenty-four hours had nearly disappeared, leaving only a certain amount of induration. This passed away, and the patient left the hospital as well as could be desired.

He asked those present their experience in regard to the mortality in recurrent attacks. A large collective experience on this point was necessary for our guidance in advising in such cases. It was possible to suppose, as Dr. Partridge had suggested, a condition of the appendix in which a recurrent attack might be a source of the gravest danger.

Dr. Bull read the following communication from Dr. Weir, who had just sailed for Europe:

"New York, February 3, 1890.

"My Dear Dr. Bull: Will you kindly add my view to your own concerning the important question of intermediate laparotomy for quiescent recurrent appendicitis. Our views as surgeons have been so largely made upon the idea of a perforative or gangrenous appendicitis, that I think the milder lesions of an inflamed or stenosed appendix, with, in the latter, retention of secretion, has not been sufficiently considered as a possible cause of the lighter attacks, that are more frequently seen by the general practitioner than by the surgeon. More should be known of the natural history of this form of the affection, before accepting the dictum that an operation should be employed in recurrent attacks to prevent a possible, or even probable, danger. I have only seen, in some fourteen removals of the appendix, one in which the perforation was caused by retention of fluid by stenosis, and in this the abscess progressed slowly. All the others were perforated by concretions or foreign bodies, in which cases, according to Pawlowski, a more intense infection of the peritoneum is to be expected. Moreover, as far as I can learn, in none of the rapidly increasing number of cases in this city operated on recently to prevent a repetition of appendicitis, has there been any perforation or any decided indications of peritoneal changes found when the appendix was exposed. I have felt that only such patients should be advised to submit to this intermediate operation in whom the perityphlitic recurrence takes place so often as to seriously impair their usefulness, or those who by force of circumstances are apt (by travelling and the like) to be removed from surgical supervision when an acute attack begins. Such has been the advice I have felt impelled to give in several recent cases, and I have had no reason yet of sufficient weight to make me depart from this rule. For, after all, laparotomy, however carefully conducted, is an operation of risk."

Complications of Recurring Appendicitis.—Dr. Polk could recall but two cases of recurring appendicitis which had terminated fatally. One was in a patient who developed portal phlebitis and subsequently died of pyæmia. The other had been in a patient with a similar history, related at the last meeting of the Society by Dr. Murray. These complications should be taken into consideration in estimating the probable dangers from frequently recurring attacks.

The President said, with regard to Dr. Murray's case, that there was no history and no symptoms, while the patient was in the hospital, pointing to trouble in the appendix. The symptoms pointed to abscess of the liver, which at the autopsy was found to be the result of an old appendicitis. Such cases had not been infrequently observed.

Dr. Polk then recalled a third case which he had seen, about fifteen years before, the patient dying of multiple abscesses of the liver and phlebitis, which communicated directly with the diseased appendix.

Dr. Bull said, in reply to the question, how many attacks constituted an indication for the operation? that is was the frequency of the attacks rather than the number which should be considered. In one case the attacks might be distributed over a very long period; in another, over a very short period. In one case which he had seen, the first attack had occurred twenty years ago; the second only a month ago. He thought that any person who was laid up for two or three days, or a week, or ten days, with symptoms recognized to be those of appendicitis, sufficiently often to interfere with his labor, or to make him uneasy regarding the safety of his condition, should take into consideration the propriety of an exploratory incision. In a person who had no business to attend to the symptoms might be permitted to recur for a longer time, with the hope that they would eventually cease, for all knew that in some instances spontaneous recovery did take place. In the case of the boy cited in his paper, the propriety of an operation arose very forcibly, for between March and July of one year he had six attacks, and at each attack his parents were thrown into a state of great excitement. The boy could not go to school, and the family was afraid to go to Europe. Regarding the fatality during recurrent attacks, the testimony of many physicians would prove of great value. For his own part, he seldom saw cases until the question of operating arose.

The case cited by Dr. Shrady, he thought, was an important one, for it showed that certain pathological changes could exist in the appendix and subsequently quite disappear, or else that we attributed certain symptoms to the diseased appendix which had no such origin at all. It was a curious fact that there was a number of autopsies on record in which the appendix had been found in various stages of disease, so-called, presenting thickening, adhe-

sions, stenosis of the orifice, etc., yet the history contained no reference whatever to symptoms of appendicitis. That fact cast some doubts on the symptoms of this form of inflammation, as they were known at present.

Operations for Recurring Attacks where no Pathological Changes were Found.—Dr. Bull said that, on the basis of reasoning presented in his paper, he had advised and witnessed an operation in a case in which no lesions were found which could account for the symptoms of appendicitis. The appendix contained no concretion, and there was no indication that traction could be made upon the gut injuriously because of adhesive inflammation. This patient, a physician, had then undergone a serious operation to get rid of certain symptoms attributed to appendicitis which they were unable to explain when the appendix had been presented to view. In a case which a gentleman operated upon at St. Luke's Hospital, the appendix was found simply bent upon itself, it contained no fluid, and while it was said to be thickened, it certainly did not look like an appendix which had given rise to serious symptoms. In a case operated upon by Dr. Curtis he had been told that there was pus, which evidently would have formed an extra-peritoneal, not intra-peritoneal, abscess. The condition corresponded to what Dr. Draper had mentioned, namely, successive attacks during which the inflammatory exudate had sealed the appendix from the general peritoneum, and subsequent formation of pus in considerable quantity would probably have been guided toward the exterior rather than toward the interior. But these, he said, were only questions of detail a knowledge of which served to increase the difficulties of arriving at a definite course rather than to lessen them. Yet, in a case in which there were frequently recurring attacks, he would still be willing to recommend an operation, and he would perform it with a great deal of confidence; but he could not say to the patient that he regarded it as perfectly safe.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 3, 1890.

Alfred L. Loomis, M.D., President, in the Chair.

The Fallacy of the so-called Hot-Air Treatment of Phthisis.—Dr. W. Gilman Thompson devoted the first part of a paper with this title (see p. 457) to a review of the results obtained by this method of treatment in this country and in Europe. Personally he had had no experience with it. It had impressed him as being based on false principles, and in practice likely to lead to negative, if not to absolutely harmful, results. And for this reason he had instituted certain experiments in the Loomis laboratory to determine whether or not the inhalation of hot air could destroy or arrest the development of the tubercle bacillus in the lungs, for this was in fact the object of treatment.

He used a coiled iron cylinder connected with a bellows, the cylinder being heated by a Bunsen burner. Thermometers were placed in the straight horizontal part of the cylinder at varying distances from the nose of the animal inhaling the hot air, and also in the trachea and thoracic cavity. The following case was an example of a number: In a bitch the temperature in the lung previous to the inhalation of hot air was 102.3° F. She was made to inhale for more than an hour air above 200° F., but the temperature in the lung and of the body remained unchanged. The inhaled air was raised to 290° F., when the animal became very uncomfortable and restless, there was evidence of local irritation from the heat, profuse salivation, reddened and swollen tongue. Under these conditions the body temperature rose 1.8°, but as great a rise had been observed in dogs subjected to almost any kind of operation. In the case of a cat the temperature of the inhaled air at the mouth was 250° to 270° F., continued an hour, the animal showed very decided discomfort, but the temperature rose only two degrees. In another case the lungs of the dog were removed, hot air at 300° F. forced in for nearly an hour, a thermometer placed directly into the lung tissue, yet it was impossible to raise the temperature more than three or four degrees. These experiments showed that when air at a temperature of 300° F. was forcibly driven into the lungs, the moisture was still sufficient to cool it to nearly the temperature of the body.

In view of the statement which had been made that a temperature of 102° F. retarded the growth of the tubercle bacillus, it was interesting to note that the normal temperature of rabbits was 102.5° F.; of the guinea-pig, 103° F.; of the pigeon and fowls, 108° F., yet it was well known that all these animals were readily affected by tuberculosis.

It had also been stated that the inhalation of cold air was noxious to the tubercle bacillus, and that pulmonary hemorrhage could likewise be checked in that manner. By experimentation he had been able to refute this view also. A dog was made to inhale air below 40° F. an hour and a quarter, yet the temperature in the lung fell only two degrees. A fall of this amount would never prove sufficient to control hemorrhage from the lung by vaso-motor contraction.

The conclusions from his experiments were: 1. That the continued inhalation of air heated from 200° to over 300° F. at the nose did not raise the temperature of the lung at all in some cases, even when inhaled an hour or more; in other instances there might be a slight rise, from two to four degrees, due to other causes. 2. The temperature of the trachea under corresponding conditions rose only four to six degrees. 3. Cold air did not affect the temperature of the trachea or lungs any more than did hot air.

The experiments showed the uselessness of the so-called hot-air treatment of phthisis. Since making them he had learned that like conclusions had been arrived at by a Frenchman.

Dr. J. Lewis Smith discussed the paper and said that about two years ago a brother of Weigart was given permission to try his apparatus in the treatment of some cases of tuberculosis in the wards at Charity Hospital, but the patients were not as much benefited by this new method as by antiseptic inhalations.

A Study of Cerebral Palsies of Early Life, Based upon an Analysis of One Hundred and Forty Cases.—Drs. B. Sachs and Frederick Peterson were the authors of the paper. It was read by Dr. Sachs. All the cases reported, with few exceptions, were examined by one of the authors. A number were seen through the courtesy of Drs. Gibney, Townsend, and Gray. In two recent ones autopsies were made, a matter of importance, since few had been recorded in literature. Few nervous diseases were better understood than infantile spinal paralysis; but about few was less known than about infantile cerebral palsy. We should no longer be satisfied to recognize simply spastic hemiplegia, diplegia, or paraplegia, but should attempt to determine the special morbid condition underlying each form. First, a clinical study of the cases was made, a few reported in full, tables arranged of the various features. Of the 140 cases, 87 were males, 53 females; 105 were hemiplegias, 24 diplegias, 11 paraplegias.

Case I. A. F——, aged four, male, first child, difficult labor and instrumental delivery. From very first day right hemiplegia. Slight athetosis and associated movements. Contracture at elbow, formerly pes equino varus improved by operation. All reflexes of right side lively. Mental condition fair.

Case VIII. H. K——, male, aged twenty two months, acquired right hemiplegia, onset at six months, following convulsions during pertussis and pneumonia. Trace of weakness in right arm; distinct spastic paralysis of right leg; knee-jerk exaggerated; feeble-minded. This case made at first the impression of a monoplegia.

As much as the cases differed from one another they

also had much in common. The child was either born with, or in its early life developed, some form of paralysis—a hemiplegia, a diplegia, or a paraplegia. In congenital cases there had been some disturbance during pregnancy, or the labor had been tedious and difficult, or definite cause could not be given. In the acquired cases the onset of the paralysis might occur after acute infectious diseases, during convulsions, or from causes which could not be fathomed. In all the cases there was more or less retardation of growth, all stages of mental impairment, but a few of good mental development. No changes in sensibility were observed, and the electrical reactions were never markedly altered.

Diplegias and paraplegias were more likely to be of congenital origin, hemiplegias to be acquired the first three or four years after birth, yet over twenty per cent. of all the hemiplegias were congenital. Diplegias and paraplegias were comparatively short lived, hemiplegias often attained a very considerable age.

It had been doubted whether aphasia followed the same laws in infantile hemiplegia as in the adult form. Aphasia could be said to be present if the hemiplegia came on in an individual who had already acquired articulate speech, say after the second year. They had records of seventeen cases of hemiplegia with undoubted aphasia; of these ten were cases of right hemiplegia and seven of left.

The reflexes were either lively or exaggerated in the large majority of cases. Disturbances of motion, such as choreiform athetoid associated movements, were observed with unusual frequency after hemiplegia, and, as they had learned, also after diplegias in children. Such disturbances of motion after single and double hemiplegias had an unusual interest; they all pointed to some interference with the proper transmission of motor impulses, either of the voluntary or of the inhibitory kind. Rigidity, with contracture, was one of the cardinal features of all these palsies. Why flexor and not extensor muscles, abductors and not adductors were the seat of contracture, was a puzzling question. It was, probably, due to the mechanical principles involved in the construction of joints. As to trophic disturbances, there was likely to be disturbance of circulation in the limb, causing livid hue. There was retardation of growth.

The association of epilepsy with infantile cerebral palsies was, perhaps, the gravest feature. It was present in 44.3 per cent. of all their cases.

As to cranial defects, in most cases of hemiplegia there was flattening of the skull on the side of the lesion, and in almost all cases of cerebral palsy most of the cranial diameters were below normal averages.

They had analyzed the records of one hundred and five autopsies, including two of their own. The most conspicuous feature of this table was the prominence given to atrophy, sclerosis, and cysts, but all these were terminal conditions and were almost useless for the determination of the initial lesion. We were forced to rely upon cases in which the initial lesion had not disappeared, and here the first fact which was brought out with great distinctness was that hemorrhage, thrombosis, and embolism, the conditions which gave rise to adult apoplexy, were also found to be a frequent cause of the cerebral palsies of early life.

Regarding the polio-encephalitis of Strümpell, or polio-encephalitis corticalis, he asked what proof had we there was such a condition? Anatomical proof, none. They were willing to concede that some of the many cases of atrophy and sclerosis may have been due to this polio-encephalitis, but it was unfortunate for Strümpell's theory that all of the autopsies made soon after the onset of the disease had shown other conditions, and not a polio-encephalitis.

Meningeal and cortical hemorrhages were shown to be more frequent in children, while any other cerebral hemorrhages were more frequent in adults. This would explain the more serious character of the symptoms in the young, and the more frequent occurrence of epilepsy and mental impairment in them.

Regarding symptoms depending upon location or extent of the hemorrhage, they said that if one could exclude embolism, and sudden and very large hemorrhage, and lesions of the lower gray centres, the absence of convulsions at the outset of an apoplectic attack was in favor of a lesion in the interior of the brain rather than in or upon the cortex. Of this he was more certain, that whatever might be the symptoms accompanying the onset of an apoplectic attack, if the convulsions reappeared after the initial symptoms the lesion was cortical, or else an additional injury had occurred.

The autopsy in one of their cases (Dr. Peterson's) was on a boy aged twelve, who began to have headaches when about nine years old, and went on to have loss of memory, steady progress toward dementia, toward the end an epileptic fit, right hemiplegia, constant right-sided hemiepilepsy. The autopsy showed on the right side, subdural space seat of a limited pachymeningitis hemorrhagica interna, but merely a thin organized detachable stratum of long standing. Over the left side the pachymeningitis was very wide spread, over the convexity of the hemisphere the hæmatoma was very thick, some of the strata undoubtedly dating from the beginning of the symptoms. Between two and three ounces of fresh coagula were spread on the convexity, especially in the Rolandic region. There was no disease or injury of the cranial bones, no lesion in the interior of the hemispheres, ganglia, pons, or medulla.

As bearing on the question whether it was possible to determine the morbid lesion by the symptoms they said:

The form of paralysis is not the most important factor in diagnosis. Acquired cases of hemiplegia and diplegia, but particularly the former, are apt to be due to the same causes that prevail in adult apoplexies; namely, hemorrhage, thrombosis, or embolism; meningeal and cortical lesions are more frequent. Absence of convulsions at onset probably point to an intra-cerebral lesion. Occurrence of convulsions at onset points generally to cortical lesions or to embolism anywhere in the brain. In a few cases affections of the gray matter lower down in the central nervous system may also be attended by convulsions. Frequently repeated convulsions after onset are more than likely due to cortical lesion. Cases coming on after acute infectious diseases have been proved to be due to vascular derangement, particularly to hemorrhage and embolism, but some cases may be due to a polio-encephalitis corticalis; the onset with very high fever and convulsions makes the latter more probable. Traumatism is an important factor in the causation of meningeal hemorrhage during early life and particularly during the act of labor. Congenital cases of diplegia and hemiplegia may be due to early encephalitis. In acquired and congenital cases of hemiplegia and diplegia we may have either a condition of porencephalus or simple arrest of development. If acquired, there would seem to be a history of slow development of the symptoms without predisposing cause. If congenital, there may be a history of traumatism to mother. In later life, hemiplegia or diplegia, associated with large amount of mental impairment and with contractures, point to general atrophy, sclerosis with secondary degeneration, or to a condition of porencephalus, the origin of which it is often difficult to determine.

A few closing remarks were devoted to the prophylaxis and treatment.

Four Causes of Cerebral Palsies in Infants.—Dr. J. Lewis Smith was asked to open the discussion, but each speaker being limited to five minutes he could read only a part of his notes, in which he divided the causes of these cases into four groups: those due to intracranial hemorrhage, to cerebral tuberculosis, to tumors, and to spurious hydrocephalus. He thought he had seen cases due to embolism.

Causes of Intracranial Hemorrhage.—The chief cause was prolonged and difficult labors. The blood clot interfered with the function of the pneumogastric, the child was born asphyxiated, and in six cases in which he

had made autopsy the lungs were scarcely inflated at all. He thought a not uncommon cause of protracted labor and cerebral injury was the injudicious use of ergot by midwives, who administered the drug sometimes hours before the termination of labor. Intracranial hemorrhage sometimes took place also in infectious diseases, and during the severe cough of pertussis leading to cerebral palsy.

Dr. L. C. Gray thought the paper was a valuable contribution to our clinical knowledge of these diseases. We all knew that the symptoms mentioned existed; that there were the types of paralysis spoken of; that the various anatomical lesions took place which were mentioned in the tables, but what we did not yet know was how to link a given set of symptoms to a given set of lesions. After all the clinical knowledge which had been gotten together, and after all the tables of the pathological lesions which had been set before us, it became simply a matter of shrewd guessing as to how we were to link them together.

Strümpell's Theory in Contempt.—He had not much respect for the theory advanced by Professor Strümpell. There was no proof of it at the time, there had been no proof of it since, and there was no *a priori* proof of it. There was not the slightest proof of it by analogy except in a most roundabout way between the motor convolutions of the cortex and the anterior horns of the spinal cord, and it seemed perfectly idle to attempt to trace an analogy between the diseases of the two parts.

It was sometimes difficult to tell just how much a child's backwardness was due to impaired mental function and how much to ignorance on account of feeling itself cast into the background from an early period. Then there were cases in which the hemorrhage took place and for a time remained stationary, then under slight treatment improved. He had in several such cases attributed the improvement to the treatment, but he afterward found that most variated treatment was attended by the same result, and probably had had nothing to do with the improvement.

Strümpell may be Partly Right.—Dr. C. L. Dana said he had been in the same state of mind as Dr. Gray regarding Professor Strümpell's views, but had more recently been inclined to think that there were some cases due to the kind of lesion described by that author. From what we knew of dural hemorrhage it would not produce such a laceration of the cortical substance. It would seem, then, that the condition in certain cases must be due either to cortical hemorrhage or to thrombosis. But it was inconceivable of a large number of pia vessels bursting and producing a deep cortical lesion, resulting in the changes spoken of, and we would have to assume, therefore, that there must have been an inflammatory disorder at the start.

Combination of Cerebral Hemiplegia and Peripheral Neuritis.—An interesting clinical phase of the disease had been observed by him in two cases, in which the peripheral throat neuritis of diphtheria had been combined with cerebral hemiplegia.

Dr. W. R. Birdsall thought there was little clinical and still less pathological data to support Professor Strümpell's theory. Although it did seem that infectious processes might be at the base of disease of both the cerebral cortex and of the gray matter of the cord, he thought the author did well to lay stress on prolonged labor as an etiological factor in the cerebral palsies of infants.

Treatment of the Deformities.—Dr. V. P. Gibney spoke of the orthopædic treatment of these cases. The most benefit was to be derived in overcoming trophic changes from want of use by employing electricity and massage and hygiene. Certain deformities were best overcome by manual force or division of the tendons. Much harm had been done by torturing these patients with braces, especially in as far as they interfered with exercise and development.

Dr. Sachs closed the discussion, and reiterated his views on Professor Strümpell's theory. It simply lacked proof, and we had better assume the symptoms were due to some other lesion until it had been shown they were due to polio-encephalitis corticalis.

New Instruments.

A NEW NASO-PHARYNGEAL FORCEPS.

By James E. Nichols, M.D.,
New York.

For the treatment of the very important and now commonly recognized disease known as chronic hypertrophic naso-pharyngitis, or adenoids of the pharyngeal vault, there have been many instruments in use with varying degrees of success. Since Loewenberg first made use of his post-nasal forceps, there have been numerous changes and modifications in his model, each one of which has, I suppose, a "raison d'être." I venture to add another to the number, for the reason that so many have expressed an appreciation of its excellence, and not with any claim to great originality. The main objection to the forceps of the Loewenberg or Hooper type is that having only a pinching edge with very small space between the blades when closed, the adenoid tissue is not cut off in a cleanly, efficient way, but rather torn off in bits of varying size, according to the strength of the pinch, and the grasp of the pincher. The result is a more or less roughened surface, and in many cases a stripping down of the pharyngeal mucous membrane, followed by unpleasant cicatrices. It is always advisable to leave as smooth a surface as possible after an operation of this nature, in order that speedy healing may take place, as well as the diseased tissue be entirely eradicated.

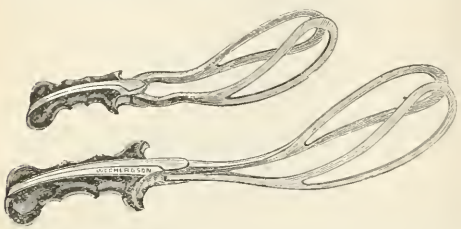
The forceps shown in the accompanying cut have proven successful in this respect. The curve of the scissors blade is such as to fit the vault's normal curve, and the cutting edge is long enough to cover the origin of most growths. Being fenestrated, a very large amount of tissue can be removed at one grasp, and I have rarely found it necessary to introduce the instrument more than twice on one patient. The scissors handle is believed to be more manageable than the straight handle, with spring, of the Gradle forceps, from which the principal features of the instrument are derived.

NEW OBSTETRICAL FORCEPS.

By C. D. Palmer, M.D.,
Cincinnati, O.

Dr. C. D. Palmer, Professor of Obstetrics and Gynecology in the Medical College of Ohio, and Gynecologist to the Cincinnati Hospital, has, with the valuable mechanical assistance of Max Wocher & Son, of Cincinnati, instrument manufacturers, gotten up a new forceps. The following are the points: Long forceps, weight, 18½ oz.; length, 14.5 inches; fenestræ, 4.81 inches; distance between blades, 2.87 inches; distance between tips of blades, .75 inch. They have a good pelvic curve, and a double cephalic curve in blades, and an English lock.

The handles have a slight backward curve, equal to forward curve of pelvic blades. There are tractors on the handles, which consist partly of wood and partly of metal.



The short forceps have a weight of only 12 oz. and a length of but 11.27 inches. The fenestræ of the blades are 4.18 inches long. The shanks are like Simpson's, with English lock. The distance between the blades at their widest part and at the tips is about the same as the long forceps. The handles have the backward curve also.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 13 to April 19, 1890.

Baily, Joseph C., Lieutenant-Colonel and Assistant Medical Surveyor. By direction of the Secretary of War, leave of absence for two months, on surgeon's certificate of disability, is granted, with authority for his admission to the Army and Navy General Hospital, Hot Springs, Ark., for treatment therein. Par. 10, S. O. 85, A. G. O., April 11, 1890.

Brown, Paul R., Captain and Assistant Surgeon, now at the Army and Navy General Hospital, Hot Springs, Ark. By direction of the Secretary of War, is relieved from station at Fort Thomas, Ariz., and will report in person to the commanding officer, Little Rock Barracks, Ark., for duty at that post, reporting by letter to the commanding general, Department of the Missouri. Par. 3, S. O. 84, A. G. O., April 10, 1890.

Middleton, Passmore, Major and Surgeon (St. Francis Barracks, Fla.). Leave of absence for two months, on surgeon's certificate of disability, is hereby granted. Par. 1, S. O. 85, Headquarters Division of the Atlantic, April 12, 1890.

Stephenson, William, Captain and Assistant Surgeon. By direction of the Acting Secretary of War, so much of paragraph 2, S. O. 83, A. G. O., April 9, 1890, from this office, as directs his transfer from Fort Verde, Ariz., to David's Island, N. Y., is so amended as to substitute the words Columbus Barracks, O., in place of David's Island. Par. 1, S. O. 89, A. G. O., Washington, D. C., April 16, 1890.

Mattews, Washington, Major and Surgeon. By direction of the Secretary of War, is relieved from duty in the Surgeon-General's office, this city, and will report in person to the commanding officer, Fort Wingate, N. M., for duty at that station. S. O. 90, par. 6, A. G. O., Washington, D. C., April 17, 1890.

Cleary, Peter J. A., Major and Surgeon. By direction of the Secretary of War, is relieved from duty at Fort Wingate, N. M., and will report in person to the commanding officer, Mount Vernon Barracks, Ala., for duty at that station, and by letter to the commanding general, Division of the Atlantic. S. O. 90, par. 6, A. G. O., Washington, D. C., April 11, 1890.

Official List of Changes in the Medical Corps of the United States Navy for the week ending April 19, 1890.

Beyer, H. G., Passed Assistant Surgeon. Ordered to the Yantic.

McCarty, Rufus H., Passed Assistant Surgeon. Died April 12th, with pneumonia, on the Yantic, at Key West, Fla.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 19, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	12	1
Scarlet fever	98	5
Cerebro-spinal meningitis	4	3
Measles	341	31
Diphtheria	116	32
Small-pox	0	0
Varicella	20	0
Cholera	0	0

The Old Fairfield Medical College.—At a recent meeting of the Oneida Historical Society, held in Utica, Dr. L. B. Wells contributed an interesting paper on the Fairfield Medical College. The school was established by the trustees of the Fairfield Academy in 1809 and at once acquired a good reputation. This was so great that in the second year of its existence the legislature of the State gave it a present of $5,000, and when it was chartered as a college in 1812, an additional grant of $10,000 was made to it. The charter of the college bears date of June 12, 1812. At a meeting of the Board of Trustees, held December 1, 1812, the following individuals were appointed officers of the college: Lyman Spaulding, Professor of Anatomy and Surgery; Westel Willoughby, Jr., Professor of Obstetrics; James Hadly, Professor of Chemistry; John Stearns, Professor of Theory and Practice of Physics. The class of 1812–13, as appears by the records, consisted of 18 medical students. During the session of 1813–14 it numbered 24. At a meeting of the Board, March 23, 1815, T. Romeyn Beck was recommended to the honorable regents to fill the office of Professor of the Institute of Medicine. January 30, 1816, the degree of Doctor of Medicine was conferred on two individuals, viz.: Horatio Orvis and Sylvester Miller. Dr. Beck gave his first course on medical jurisprudence. The number of students increased steadily up to the year 1834, in which year there were 217 students, of whom 55 received the degree of M.D. The following year the number was 198. The organization of the medical department of Geneva College, and subsequently the incorporation of the medical college in the city of Albany, together with other causes, had the effect to diminish the number of students in attendance at the Fairfield College. The last course of lectures was given during the winter of 1839–40. The number of students was 105, of whom 26 received the degree of Doctor of Medicine. Since the cessation of medical lectures the college buildings have been occupied by the Fairfield Academy. Dr. Lyman Spaulding was the first President of the college, and was succeeded in the office by Dr. Joseph White, who held the chair from 1817 to 1827. Dr. Willoughby was then elected to the office and held it until his death.

Perhaps the Sovereigns had Good Cause for Gratitude.—The late Dr. Philippe Ricord, of Paris, was the most decorated man in Europe, having more than two hundred crosses, medals, and other insignia of gratitude and admiration bestowed upon him by European sovereigns.—*Canada Medical Record.*

INDICATIONS FOR ABDOMINAL SECTION AND THE DETAILS OF ITS PERFORMANCE.[1]

By LAWSON TAIT, Esq.,

PRESIDENT OF MASON'S COLLEGE AND PROFESSOR OF GYNECOLOGY IN QUEEN'S COLLEGE, BIRMINGHAM.

I FEEL that no small amount of responsibility is involved in appearing before you in the character of an instructor, and it entails a good deal of care in the choice of a subject as well as in the method of dealing with it. It has occurred to me that as useful a means of complying with your request as any, would be to answer some of the questions which are constantly being addressed to me as to the details of the operation with which my name is associated, viz., the operation to which I prefer to give the English name of abdominal section; and if, for the sake of simplicity, I deal with the subject in an elementary way, I must ask you to believe that it is not with the desire to treat you as second- or third-year students, but in order to give you answers to questions which appear to those who make them to be of a high degree of importance. The great success which has attended the practice of some of us in this department has excited a great deal of curiosity among many of the visitors, especially from foreign countries, who come with the belief that I have some secret, concealed method, which I have not yet made public, either of destroying germs or otherwise, with which they are very desirous of becoming acquainted. I, however, know of only one means by which our success has been obtained, viz., by reducing everything in the details of my operations, in their inception and in their carrying out, to the verge of simplicity. You will, I am sure, agree with me that therein lies a very large amount of success. Hence, I have chosen for the title of my remarks to you "The Indications for Abdominal Section and the Details of its Performance." Upon the first part of this title one might speak for a month or two, but I propose in this respect to keep myself to the wide question of the indications for abdominal section; I mean, of course, in accordance with the teaching of the modern school of surgery, and by that I mean a school which has come into existence within the last ten years or so. This modern school stands in opposition to the older school, which holds views widely removed from and opposed to ours upon this very question of what constitutes the indications for abdominal section. Only ten years ago the operation of opening the abdomen was regarded as a proceeding fraught with very great danger.

If exploratory incisions existed at all before 1878, they were generally the results of a mistake rather than of deliberate intention. The surgeon would make a diagnosis and proceed to operation, and when he opened the abdomen he would find that he had made a mistake, and he proceeded no further. That might be called an exploratory incision, but that would hardly come within the meaning of what is now known as an exploratory incision. At present we make a diagnosis, we exercise all known means of arriving at a correct conclusion, and even then we know but too well that there is ample room for error; and that field of possible error is the field we traverse by our exploratory incisions. I may mention as *apropos* of this distinction a case which occurred in the neighborhood of Leeds, to which I was called by Mr. T. R. Jessop, for the purpose of operating. It was a case in which he and the medical attendant had diagnosed, for very good reasons, ruptured tubal pregnancy. When I saw the patient I was under the impression that the case was one of suppuration at the base of the kidney, a view which was not at all consistent with the clinical history of the case. Mr. Jessop was good enough to say that my opinion might be correct, but he thought not; but, seeing that the patient was very ill, it was agreed that we should settle the question the next day by an exploratory incision. The following day, therefore, we proceeded to open the patient's abdomen. I opened up a suppurating cavity, and put my finger into what we all satisfied ourselves was the pelvis of the kidney, and I removed concretions, apparently of renal origin; yet we turned out to be all in the wrong, for it proved to be a case of perityphlitis, a possibility which had not occurred to any of us, though it was a case in which as much skill and care as could be used had been employed. The history had been most carefully gone into, and even now, in going over the case, I do not see how we could have come to any other than our erroneous conclusion.

The lesson to be drawn from that case is not to be too cock-sure of one's diagnosis, but to open the abdomen, find out what the condition is, and then do your best to remedy it. Now, I have been subjected to gross misrepresentations on this point. It has been repeatedly said that this rule simply means opening the abdomen for the fun of the thing. It is certainly rather the converse of the old school, but our principle is not to stand in the way of our patient's recovery, and when the suffering is such as renders life unendurable, not to allow ourselves to be deterred by some fancied fear of opening the peritoneal cavity, from seeing what can be done to alleviate the condition. The mortality is so slight under ordinary circumstances that the result cannot well be expressed in percentages. I do not say that exploratory incisions are never fatal. They are so to the extent, perhaps, of two or three per hundred, but this result must be taken with the qualification that the exploratory incision is often made in cases which are quite hopeless from the beginning, such, for instance, as one recently at Southport, in the case of a patient who was supposed to be suffering from gall-stones. I felt satisfied at the time that it was a case of cancer of the liver, and not gall-stone at all, but the condition of the patient was such that I thought it was desirable to afford the patient a chance of relief, however slender.

Why, you may ask, did I make the incision? Simply because the patient and her friends had danced about from one physician to another to an extent that was damaging to the patient, beneficial to nobody, and excessively annoying to the medical man in attendance. My impression that it was a case of cancer of the liver would not have been likely to outweigh the half-dozen opinions of the others, who had concluded that the patient was suffering from something else.

I opened the abdomen by a two-inch incision, and settled definitely that the case was one of cancer of the liver. This patient did not suffer at all from the incision, and without it she must have died all the same; but if the operation had not been performed, a continued uncertainty would have added much to the discomfort of all concerned. Even the mortality of three per cent. must, therefore, be discounted, in that such deaths are complicated ones and not due solely to the operation. Let me take for another example a case of intestinal strangulation with fecal vomiting. You have an idea that there

[1] An address delivered to the Cardiff Medical Society.

is intestinal obstruction, but you have not a suspicion where the obstruction is situated. In such a case you open the abdomen, prepared to do the best you can. You may find it to be a case merely of acute peritonitis and your patient may die unrelieved, yet this result cannot fairly be placed entirely to the account of the operation. The complete justification for the operation is the extreme illness of your patient, concerning which the diagnosis may appear perfectly clear to you; but there is always the possibility that you have been mistaken, and that the condition be really one which might have been overcome by timely intervention. This supplies a justification which is largely limited to cases in which disease is diagnosed in a very early stage, or where the condition is very acute, as in the condition of acute strangulation, or in the case I have related under Mr. Jessop. It is in chronic cases that the second justification for exploratory incision is to be found. This brings us into the second great group of cases, which I will not define, but of which I may give you instance after instance. Take for example a case such as this: A girl, aged fourteen, just beginning to menstruate, has a bad attack of scarlet fever. You inquire into the history, and you find that it occurred when she was at school. There were no particular pelvic symptoms, but ever since the girl has complained of intense abdominal pain, interfering with her convalescence. This girl has begun to menstruate, but her periods are irregular. If you adopt the common course of relieving the pain by administration of morphine or opium, there is the danger of the girl becoming a confirmed narcotomaniac. As the case goes on, it goes from bad to worse. Besides irregular menstruation, the periods become invariably associated with terrible suffering. Then the patient gets married, and marriage intensifies and aggravates her condition. She is examined and found to have a retroflexion. A pessary is put in, which makes her worse. Then cervical stenosis is found, and so on until, what between the treatment and her sufferings, her life is made about as miserable as it well can be. The retroflexed uterus which has been discovered is of itself quite a harmless condition, and when it does hurt and can be relieved, the uterus is returned to its normal condition. But the climax comes in the discovery of a lump the size of a Tangierine orange on each side of the uterus, and, briefly, the case turns out to be one of ovaritis, with adhesions and probably occlusion of the tubes. The appendages become active, and the uterus is displaced downward and backward by the adhesions, and in the attempt to correct the displacement the case is converted into one of pyosalpinx.

When such a patient comes to me in my consulting-room, I have to decide the question what is to be done. The patient is twenty-eight years of age, has been married, let us suppose, seven or eight years. There is no history of pregnancy, and that fact alone is sufficient to show that there is something the matter with the generative apparatus—probably the Fallopian tubes are blocked. Now, what is to be done in such case? In the old days these cases were left alone. They went on, and a great number—perhaps fifty per cent.—died from the disease itself, or rupture of the abscess into the peritoneal cavity, with death from peritonitis. Dr. Hingston Fowler has shown that fifty per cent. of the cases in the hospital of pyosalpinx died of blood-poisoning, rupture, etc. The question is, can you say to the patient, "Your condition is such as to endanger your life?" In most cases I am satisfied you can say so. If you put the danger to life out of consideration, what can you do to relieve this patient? Is she to be condemned at the age of twenty-eight to live a life of constant misery, unable to fulfil her functions, domestic and marital? She will have to remain most of her time on her back in bed. She is not a wife, for intercourse is invariably painful in the extreme. What, then, shall we do? You investigate the story of the pelvis very carefully, and you ask yourself if she is telling you the truth. Is her suffering as serious as she makes it out to be? If she be a genuine sufferer, she will declare herself ready to go through anything to get rid of her trouble. If she accepts your advice willingly, then you bring her within the category of cases in which you are not only justified, but it is your bounden duty, to explore the pelvis and see what really is the matter, and, if necessary, to give her the relief that only a surgical operation can afford. I could give many instances in which the justification of an exploratory incision will depend upon the individual details of the case as determining the class to which it belongs.

Let me pass in review the group of tumors, for that is the one which most attracts public attention at this moment. The battle, indeed, is one which is being fought at present in the case of tumors. Victory has been decided by the mistakes of our opponents. Thus, without mentioning any names, we can point to those of the opposite school who assert in the first place that they make no mistakes in the diagnosis of tumors, and they always usefully begin with the object of preventing an accurate knowledge of the actual condition being obtained. Suppose it was true that they knew at the beginning what the nature of the tumor was, there is always this source of error, that they refuse to operate upon tumors by raising a wrong diagnosis in cases which ought to be operated upon, and the result is greatly to the confusion of those who had refused to operate. These cases are operated upon now almost daily. There were men who say, "We will not operate upon tumors of the uterus after the age of forty!" When a woman comes to them with one or other of these conditions, they refuse to operate. Then she is seen by a younger man. She is twice the size by then, and, what was probably not apparent before, viz., fluctuation, can be detected. The younger man says this is a parovarian tumor, and it is very easy and not at all dangerous to take out. The first man has to confess his mistake. Now, this was not the older man's fault nor the younger man's merit. If *A* had been wiser in his generation, he would have recognized that the patient is a fat woman, in whom the appearance of the primitive sign of fluctuation can easily be mistaken or overlooked, for no hand has ever yet acquired the skill to detect moderate fluctuation through an abdominal wall two or three inches thick. When the tumor has grown, and fluctuation is very much easier, the diagnosis is by no means difficult. Had *B* seen the case first, he would not have been able to say what it was, but he would have concluded that it would be safer to look and see, and he would have advised an exploratory incision. Then the mistake would not have occurred.

I would like to point out that these mistakes ought to be diminished in number, and exploratory incisions afford the means of so doing, for they obviate the risk of allowing a patient to remain for years under the cloud inseparable from the belief that she is suffering from an incurable disease. Such a course of events cannot but prove very damaging to *A*, and lastly it is very damaging to our profession. It should, therefore, always be our object to avoid such errors.

Having laid down the lines upon which I carry out my exploratory incisions, let me show you how it is done. It may be useful to have the minutest details before you, especially by one who has had great success, and who has always striven after the greatest simplicity. Visitors always remark that my operations are simpler far than anything they have ever seen before, particularly continental operators, who have a very complicated system. Simplicity is as efficacious as it is inexpensive. I will first show you the instruments I use. Here are two pairs of forceps which cover all the ground, and I have a dummy here which will serve to put you up to the "wrinkles" of the operation. First, as to the preparations: I never operate upon a patient, if I can help it, unless she has been under my care for at least forty eight hours. I train my own nurses. The ordinary hospital-trained nurses are a nuisance. I like to have absolute control over my patients, and this is not possible with an ordinary-trained nurse who has been under some other surgeon, for she is probably imbued with his

ideas and takes every opportunity of unfavorably comparing your method of proceeding with that of the man who had the training of her, and she has ideas of her own which obtrude themselves when least wanted. Then I place the patient upon a narrow bed with a spring mattress, and give her a slight laxative on the evening before the operation, an enema in the morning. This gives the intestines a rest for three or four days. Then she is put upon a narrow table to be operated upon; the anæsthetic we use is a mixture of two parts of ether and one of chloroform for patients under forty-five, and for patients over forty-five I increase the proportion of chloroform. If over sixty, then chloroform alone. My confidence in these proportions is based upon clinical experience. I am quite convinced that ether is a far more dangerous anæsthetic than chloroform, on account of the bronchial irritation and of retching and struggling to which it gives rise. If chloroform does kill a patient, it does so at once, and there is an inquest and a lot of trouble; whereas, if the patient dies a week later from bronchitis or some other complication, after ether, the death is not attributed to its proper cause.

On the whole, therefore, I have come to the conclusion that a combination of the two is best. The anæsthesia is a matter of great importance, and the anæsthetist is bound to attend to his patient, and do nothing else. I have another assistant who is not to open his mouth, and whose only duty is to do what he is told, and that, as a rule, is very little. Then the instruments are laid out on the table, and every care must be taken to insure that they are perfectly clean. I always keep the instruments in trays, under water, in order that the blood, etc., may be washed off, and so that I do not run the risk of introducing dead matter into the wound, such as coagulated blood. It is the nidus for germs that is to be feared, and not the germs themselves, and your every care should be to have nothing about that could serve as a soil for their growth and development. I use plain water, no kind of chemical compound. The sponges are always a source of considerable anxiety, and I have an intelligent person who does nothing else but clean my sponges. She washes them, wrings them out, and dries them and keeps them, for so long as they are dry they are incapable of decomposition. For the purposes of the operation I count them myself, and then place them in a basin that is perfectly clean and pour on tap-water. It is very important to count the sponges, and you cannot be too careful or take too many precautions, for even in spite of every conceivable precaution you will sometimes have trouble. For instance, in one case my assistant tore a sponge in two. That made thirteen instead of twelve, and I did not know the fact. I always count them myself, and then one nurse is told off to see after the sponges, and she is responsible to see that these twelve sponges are outside the woman at the close of the operation. None but myself and this nurse touch the sponges, and this is very important. All these precautions may seem foolish to you, but if you saw the kinds of accidents that happen, you would agree with me that no detail is unimportant enough to escape attention. Now, as to the operation: Make your incision, two to four or five inches in length, through the skin down to the tendon. Then cut through the tendon with a touch of the knife until you see the margin of the rectus muscle, then seize the sheath and slit it open. I have a method of opening the peritoneum which I shall be enabled to show you on the dummy better than by words. You take hold of it with one pair of forceps, which you hand to an assistant to hold. Then seize it afresh with a second pair of forceps, at about the same spot, and apply sufficient traction to put the peritoneum gently on the stretch. It is thus raised above the subjacent structures, and a slight touch with the knife will suffice to make an opening. I complete the opening by passing the finger into the opening, and nicking the membrane with the knife. As soon as the first opening is made, the intestines shrink away, and there is little danger of their getting wounded with the most ordinary care. The incision should always be made in the middle line, unless you expect the tumor is eccentric. I divide incisions into eccentric and centric. Centric incisions comprise those which deal with tumors presenting under ordinary conditions—pelvic tumors, ovarian tumors, and uterine tumors, etc. Eccentric abdominal incisions are such as you are obliged to make leaving the point of election and going elsewhere. There can be no absolute rule. Directly you get into the realm of eccentric cases you must deal with each case upon its own merits. Attack your tumor at its most presenting point, for it is growing in the direction of the least resistance. In all probability the point of resistance will be influenced by the great bulk of the tumor, that is to say, the bulk will be found in the axis of the direction of growth. The site at which it will present will be the point at which least tissues will be found, and, therefore, all the less to cut through. Any attempt, therefore, to lay down any law binding you to any one form of incision, is to expose yourself to error. Attack your tumor, whatever it is, at the most prominent part. The kidney in one place is best attacked in the loin, and in others from the front.

Ten days ago a kidney was removed by me through the linea alba. Had I known what it was, I should have made a most fearful hash of the case, for I should have cut down on the left kidney, whereas it was the right kidney that was diseased. A young lady was sent to me with distended gall-bladder, which I mistook for a parovarian tumor. I could never have got the gall-stone out had I made the ordinary incision. In the centric incision the hemorrhage is very little. The instrument next in importance and order after the knife is the scissor artery-forceps. I have a pair of Koeberle's forceps given to me by Koeberle himself in 1870, long before the instrument was known anywhere in this country, and the credit of the invention ought to be given entirely to him. The branches are made so as to exercise a powerful compression, and the handles are arranged so that you can twist the instrument easily. Ordinary retractors are sources of great trouble, and all kinds of special apparatus have been invented without finding anything so good as the ordinary forceps. The more you diminish the number of instruments, the easier they are to keep clean and your assistants can understand them. Forceps, therefore, are to be used as retractors. Closure of the wound is to be effected with needles, with common Chinese silk. Silk is an entirely animal structure, but you must take care to have it pure. It ought to be entirely soluble in caustic potash; if it leaves any residue, then there is some cotton mixed with it. I have examined the pedicles of ovarian tumors years after the operation, and there was not a trace of the ligatures. Occasionally, however, sinuses will form from the death of the ligature. I use a straight needle with a bayonet point, as less likely to cut structures in contact with it. After the operation you may have to adopt the principle of draining, and there is only one name to be attached to the principle of abdominal draining. Koeberle gave me the original drainage-tube in 1864. He used them for years before he could induce anyone else to use them. Now as to the conditions under which drainage is desirable—where you have a fear of hemorrhage, in the case of a rotten pedicle, for example. A few days ago I removed an ovarian tumor from a lady who had been confined only a few days before. The pedicle was immensely influenced in its character by the changes that were going on in the uterus, and it was very brittle and the ligature cut through. There I was very anxious to obtain early information of any possible hemorrhage. I simply dropped the pedicle back and put in a drainage-tube, telling the nurse to let me know if there was any oozing. Had there been any hemorrhage, I should thus have known it at once, and that is important, for death from hemorrhage in these cases is not altogether unknown.

The drainage-tube has reduced our mortality from ten to fifteen per cent. The older the patient, the more need

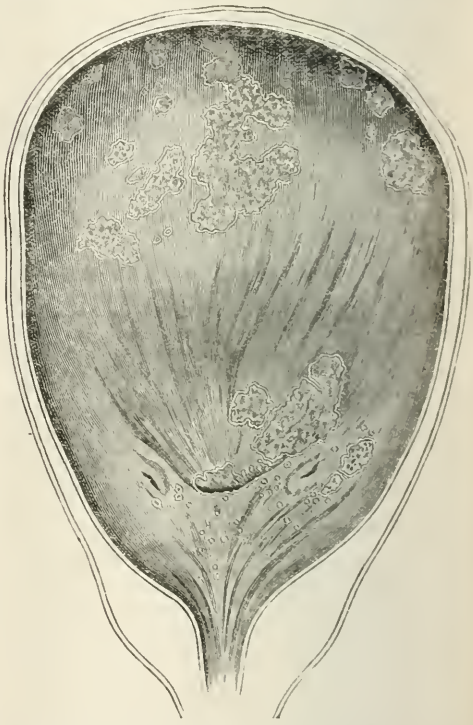
she has of a drainage-tube. I wash out the abdomen with a stream of water from a bucket; and by means of a strong current I get rid of all the rubbish from the crannies and crevices. Even oozing from adhesions may be stopped by a current of water like this. Then as to the after-treatment; the patient is put to bed, not allowed to see anybody, and the great bulk of cases recover without any great difficulty. Hysterectomy cases are always very troublesome. The method of the patient's recovery is troublesome. They will sometimes go wrong five or six weeks after the operation is apparently successful. The after-treatment is conducted practically by the nurses. For the first twenty-four hours the patient is not allowed to swallow anything at all, except perhaps a little warm water. The practice of giving ice to suck is a bad one, for the effect is to make the patient more thirsty than before, and to make her mouth sore. Vomiting is a very serious complication after an abdominal section, but the best way to avoid vomiting is not to give the patients anything they can vomit. They may have a teaspoonful of warm water from time to time to rinse out the mouth in order to relieve the thirst, and that is all. It is a little trying for them, but if you have a deprivation of fluids in the stomach, and a tendency to effusion of fluid into the peritoneum, my belief is that the deprivation of fluids in the stomach favors the absorption of the effusion in the peritoneum. The second day I give a few tablespoonfuls of milk and soda. The third day is the critical day, and the first indication of the secondary dangers is distention of the epigastrium, suggestive of peritonitis. What you have to do, then, is to give the patient a small saline purge and a turpentine enema, and you will enable her to pass flatus. I do not care a bit for anything save distention, and I never have any trouble if it is treated at once in this way. I never see a patient more than once a day if I can help it. Taking the pulse and temperature records are of great importance. In the course of my experience many little wrinkles have occurred to me which may sound absurd—for instance, I never allow nurses to wear watches with second hands, but I give them a little sand-glass which runs for a minute, so that there is no margin for error. I take the temperature in centigrade, so that the friends of the patient may not understand it. The temperature in abdominal surgery is a matter of very secondary importance, the pulse being our great guide, and whenever it rises to 120 a minute, then there is reason to be anxious. Temperature rise alone has no value as an indication of danger, but the safest guide of all is the expression of the face. An anxious expression keeps me on the tenter-hooks, and a woman who will not keep quiet after an operation, but will go on chattering, is almost sure to die.

TUBERCULOSIS OF THE BLADDER.

By ALEXANDER W. STEIN, M.D.,

ATTENDING SURGEON TO CHARITY HOSPITAL, NEW YORK (GENITO-URINARY DIVISION), ETC.

NOTWITHSTANDING recent statements to the contrary, we are led by close clinical observation and pathological study to the conclusion that cysto-tuberculosis is by no means as rare an affection as we were led to believe. The almost unanimity with which writers speak of this as a very exceptional disease is accounted for in the main by the following facts: First, The difficulty we experience in some instances in localizing the disease. Second. Other organs are not infrequently involved, whose prominence and severity of symptoms mask the bladder ailment sufficiently to lead us to overlook it or misinterpret its meaning. Third, The bladder is seldom examined after death when there were no symptoms to call especial attention to it and the immediate cause of death points to some vital organ; and, Fourth, That attention has not been particularly directed to the pathogenic factor; we hear that the bladder was "ulcerated," but no examination was made for any micro-organisms as the cause of the ulceration. All agree that the disease is much more frequent in the male than in the female. It is said that sexual intercourse with a man suffering from genital tuberculosis is capable of exciting a tubercular endometritis, and it has been produced experimentally in rabbits by the injection of bacilli into the vagina. Of the instances recorded of primary tuberculosis of the female reproductive organs, a peculiar and a very noticeable fact is that it has been confined, in most cases, to the genital system, and that it extends very exceptionally into the urinary passages. According to Erns. who has made a collection of twenty-five cases. but one occurred in the female. This is undoubtedly because of the more perfect separation of the two sets of organs, the reproductive and the urinary, in the female than in the male. In the latter, extension of the disease occurs by continuity of surface from the reproductive to the urinary organs. But tuberculosis of the bladder does not necessarily follow



the invasion of bacilli into this viscus, for we frequently find, in tuberculous kidney, the urine charged with them and yet the bladder escapes infection. Not until this viscus has acquired a predisposition, or has, in consequence of some pre-existing pathological process become less resisting to the invasion of the bacilli, are its structures rendered vulnerable to them. It may affect all ages from the earliest childhood to old age (from three to ninety-seven years); but preferably, it is a disease of the middle period of life. It is said that tubercular disease of the lung is an exception with the pathological process as occurring conjointly in the genito-urinary organs; but, far from this being the case, the autopsy reveals tubercular infiltration in the lungs in the greater number of instances. There is a crucial divergence of opinion as regards the frequency in which the bladder is primarily or secondarily involved. According to some, the bladder is more frequently affected primarily. According to the observation of others, it is more frequently involved sec-

ondarily. Those who believe in the latter mode of infection are again divided into those who believe in the transmission of the disease to the bladder by a descending process from the kidney and others who regard the extension of the disease by an ascending process from the testes, which, according to them, are primarily the seat of disease, and this is followed by tuberculosis of the vas deferens, the vesiculæ seminales, the prostate, the bladder, and it may reach, viewed by them, as high as the kidney. Now, I can understand an ascending process as far as the bladder, but I must confess to being somewhat sceptical on the matter of the micro-organisms extending higher. In the case which I herewith present I asked myself the question, If the bladder was involved primarily, why was the extension of the process limited to one side, and why did it not ascend both ureters alike? The disease in the bladder was extensive and the duration sufficiently prolonged, but neither of the ureters was affected. If the micro-organisms spread upward from the bladder to the kidney by continuity of surface, we should expect the lower part of the ureter to be involved in the pathogenic factor, as the upper part of the ureter is affected in disease of the kidney. The lower part of the ureter may be involved in renal disease, but when the kidneys are healthy the extension of the process from the bladder into the ureters must be very exceptional.

I do not now remember to have found in my observation a single unequivocal instance in which there was an extension from the bladder into the ureters, although I have records of cases in which the disease—the kidney being not involved—has spread by continuity of surface from the bladder into both vasa deferentia a short distance. Then it is difficult to conceive how the bacilli can overcome the impediment to their progress upward by the constant flow of healthy urine from above. In the extension of the disease through the medium of the circulation, the question arises, What influence, if any, has an absorbing surface on the one hand, and a secreting or an excreting surface on the other, in the absorption into, or the elimination from, the blood of the pathogenic germs? In the lungs of the adult carbonaceous particles are always found which make their way by inhalation to the air-cells, and then penetrate through them mechanically to the surface of the pulmonary tissue, especially to the summit of the lungs, and, as do the bacilli, make their way thence into lymphatic vessels to the bronchial glands, and into the circulation. And the kidneys are frequently the seat of disease in an advanced and aggravated form, while in other organs that may be affected the process is apparently just beginning. The point that would militate against the assumption that the kidneys were the emunctories of the bacilli is the fact that the disposition of the disease is often unilateral; but may this not be accounted for by the fact that the arterial distribution, the anatomy of the two organs, may not be alike favorable for their elimination. The statement that the affecting process was "limited to an area supplied by a single branch of the renal artery of one kidney" lends confirmatory evidence to this view. And the greater resisting power of one organ is not to be ignored.' Several organs of the genito-urinary system may be simultaneously affected, independently of each other, and there may not be, or there may be, concomitant tubercular formations in other parts of the body—the lungs, the meninges, the bones, the peritonæum, the lymphatic glands, etc. Thus, I have before me the necropsy of a case with what was supposed to be an old tubercular disease of one kidney; the other kidney was healthy, as was the bladder, but the prostate was extensively involved; tubercular deposits were also manifest in the lungs. Now and then we find the urinary organs alone affected, and when this is the case, one or both kidneys are the seat of the primary disease; the kidney and bladder are not infrequently involved, but cysto-tuberculosis, *per se*, if it ever occurs, is very exceptional.

It is a very interesting experience of Socin that a man may have tuberculosis of the urethra and prostate for years without involving the bladder. It is often a nice point to determine where the primary manifestation developed itself. We cannot always judge by the extent or the apparent duration of the lesion, as the process may progress more or less rapidly in the one or the other organ according to circumstances.

We see this illustrated in a measure in the specimen. Although the microbes had their starting-point presumably at the bas-fond, they made more rapid progress at the summit of the bladder, where the ulcerations are large and many and where no miliary nodules are discernible. The tubercular infiltration occurs at first as minute granulations or elevations, and to the unaided sight they appear as grayish or yellowish nodules, of a soft, cheesy, or putty-like consistence. It is not till later that they become confluent, soften, and break through the mucous membrane in the form of ulcerations, with irregular, raised margins, somewhat undermined, and varying in depth from a superficial erosion to the involvement of all the coats of the bladder, with perforation, as happened in one of my cases—in a female, by the way. Sometimes the various stages, the nodular and the ulcerative period, are found in the same bladder. The tubercular process has a predilection for the trigone and the vicinity of the vesical neck, because the bacilli tend to gravitate in the accumulated urine, and here penetrate the submucous tissue of the bladder. The specimen I present herewith shows large ulcerations all over the vertex of the bladders and several on the margins of the trigone. There are numerous miliary nodules and one or two small points of ulceration commencing in this region.

The diagnosis of tubercular disease is often made with extreme difficulty. There are no rational or physical symptoms which are to be relied upon as distinctive of this affection; for while occasionally palpation per rectum will make out the infiltration, we arrive at data often by the method of exclusion and inductive reasoning. If there is no obstructive disease to the urinary outlet, no calculus, renal derangement, or other assignable cause for the existing vesical irritability, or hæmaturia, but other organs are affected with tubercles, the lungs, the testes, etc., there is strong presumptive evidence that we have a case of tubercular cystitis to contend with. As an element of diagnosis we must elicit any hereditary predisposition on the part of the patient. As to the constancy of the pathogenic micro-organisms in the urine, their absence is not a convincing proof of the non existence of the disease. Cases will occur in which no tubercular bacilli can be discovered in the urine, and yet, upon the necropsy, find extensive infiltration of tubercular nodules at some part of the urinary tract, and thus the true nature of the case is often not made out until after death. In the earlier stages, before the ulcerative period has arrived, the urine may be entirely free from bacilli. Nor must the occasional isolated appearance of a bacillus be regarded as indicative of disease; for these have been found in the normal secretions of the urethra, and are easily mistaken for those of tubercle. But their presence repeatedly in several samples of urine is pathognomonic of tubercular disease of the urinary tract. According to Tavel, the tubercular bacilli always gravitate to the bottom, being as heavy as pus corpuscles, while other bacilli that may exist in the urine float in the water and are poured off with the supernatant fluid. He further says that they never occur in the bladder singly, but always in masses. Of course we will avail ourselves of the light, in a double sense, which the cystoscope will afford in determining the situation and extent of the process in the male. In the female my vesical dilator and speculum, will throw the field so clearly before our vision as to leave little to be desired. In the use of the cystoscope it is necessary to manipulate with the greatest care and delicacy, for in the ulcerative period especially, when these are located in the vicinity of the vesical neck, there is danger of exciting a hemorrhage, which will ob-

scure the field of vision. The life history of the tubercle bacillus is, as a rule, progressive but slow. It does not call forth any disturbance for a long time after the germ has implanted itself. The course of the disease depends upon whether other organs are similarly affected. When it is localized to the bladder it is surprising how long this viscus will tolerate the micro-organism. The symptoms can last for years (fifteen or twenty). The disease may be latent for a long time, without symptoms referable to the bladder, until other organs, especially the lungs or kidneys, light up a destructive process. The first of the rational symptoms is some disturbance in the function of the bladder, but we must remember that we may have tubercular disease of the kidney with aggravating vesical symptoms, and yet the bladder remain absolutely free from disease. And again, we may have extensive tubercular disease of the bladder with no symptoms whatever referable to the organ itself. But frequent micturition, with a sense of discomfort, which may be one of actual pain or a burning sensation, obtains, sooner or later, in by far the larger number of cases, especially if the lesions are in the vicinity of the vesical neck; the pain may then be very acute, lancinating in character, and referred to the glans penis at the end of micturition. This is in accordance with the well-known physiological law that an impression made upon a sensory nerve anywhere in its course to the sensorium is referred to its peripheral termination.

Of course the pain does not originate in the glans penis. The source of irritation may be in the bladder and transmitted centripetally to the brain, where it is interpreted as coming from the nerve-endings. We know that a mutual nervous sympathy exists between the lower urinary tract and the kidney, as there is between the kidney and the lower urinary tract, but the greater the irritability of the bladder, notably its neck, when reflexly disturbed, is to be accounted for in the preponderance of cerebro-spinal nerves which supply this part of the viscus. In some instances there may be incontinence—the patient is frequently overtaken before he can comply with the behests of nature. In others, spasm is noted—a sudden stoppage of the stream, not unlike that observed in calculus. This may go on until, ultimately, he has retention of urine in consequence of spasmodic contraction of the sphincter. Tuberculosis of the bladder, involving the orifice of one of the ureters, may cause an obstruction sufficient to produce on that side dilatation of the ureter and hydronephrosis. The urine is at first acid and cloudy, the turbidity being due, as in ordinary cystitis, to the presence of mucus and pus. It may undergo ammoniacal decomposition, when it is decidedly viscid. Occasionally there are shreds of tissue, blood-corpuscles, etc. Now and then the ulcerations will be coated over with a phosphatic deposit suggestive of calculus, which must be negatived by physical examination. But the manipulation must always be very gentle, as the least traumatism of the mucous surface may convert a latent disease into one of great activity. The next most characteristic symptom is hæmaturia; although this may be the initial sign of the disturbance, even for some time preceding the irritability of the bladder, it may be entirely absent throughout the course of the complaint. About one-third of the patients tell us that they have never micturated bloody urine. When it occurs it appears as a parenchymatous hemorrhage, the quantity of the blood lost being small, usually but a few drops, and that, as a rule, at the end of micturition; rarely are coagula passed. The hæmaturia is usually intermittent. It may disappear for weeks and reappear again without any assignable cause, often occurring when the patient is at rest and in bed. All the symptoms may be variable in duration, subject to remissions and exacerbations before softening and ulceration takes place; there is but a slight manifestation of vesical irritability. But as soon as this period of inactivity is over and the ulcerative stage has begun, the mucous surface undergoes rapid destructive metamorphosis, and the symptoms become well pronounced.

As for treatment, irrigation of the bladder can, in the main, but wash out the products of inflammation, and thus may retard the progress of the case; for whatever influence is exerted upon the former is more or less directed upon the latter. It has been said that creasote exerts a specific influence on tubercle bacilli; that they cease to develop in its presence. But, as a rule, this treatment is not well borne. Instruments should, as much as possible, be avoided, because the little good that can be hoped for from such local treatment is more than counterbalanced by the danger of producing some traumatism to the vesical mucous membrane, thereby bringing into full efflorescence a latent disease, or, in other words, lighting up an acute attack from an existing chronic process. Whenever it is practicable the sphincter should be overcome by means of hydrostatic pressure; with the aid of a fountain syringe and a short tube in the urethra, the bladder can be washed out without the introduction of a catheter into that viscus.

There are those unfortunates in whom we can but hope to make the downward course of life more endurable. The best palliative measure is one that will give the bladder as little to do as possible, and this will be effected by a suprapubic cystotomy or by means of drainage through the perinæum. Even though the vesical symptoms are due entirely to nephritic disease, it is astonishing how much relief is obtained in some cases from an opening in the bladder. Suprapubic cystotomy has the advantage that we not alone afford the patient relief, but can attempt radical measures should the nature of his case be such as to require them. In women the dilatation of the urethra and vesical neck has afforded prompt relief, and I know of no means of effecting this so satisfactorily and safely as with Stein's[1] urethral dilator and speculum. Kolpo-cystotomy has been done in some cases, but it has nothing to commend it over the suprapubic operation, and we cannot divest ourselves of the fear of affecting the generative organs.

Radical operations have for their object the destruction and removal of the pathogenic germs. Our French and German brethren have anticipated us in this direction. Reverdin,[2] after a suprapubic cystotomy, introduced into the bladder a small electric lamp of the size of an ordinary lead-pencil, by means of which the smallest lesions on the vesical mucous membrane were distinctly seen. These he scraped away with the curette and cauterized the scraped points with the thermo-cautery. Bardenheuer,[3] a little more heroic, excised the entire mucous membrane from the bladder of three tubercular patients, with encouraging results to a repetition of the operation.

We learn from the experience of Schatz,[4] in which he excised the mucous membrane, that the disease recurred after some months, and that some of the smaller nodules may easily escape detection and remain as new points of infection.

Necropsy.—Man, aged twenty-seven. Right lung adherent, otherwise normal; left lung, at apex tubercular nodules, varying in size from miliary points to that of small hazel-nuts. Heart, normal. Liver contained a large number of tubercles, with foci of suppuration. The mucous membrane of the intestines was intensely injected; several small ulcers in lower portion of ileum. Throughout the mucous membrane of the ileum, near the blood-vessels, are thousands of miliary nodules. A large number of points over the cortex and at the base of the brain. Old pachymeningitis on the left side; miliary tubercles under capsule and in the secreting substance of one kidney. There was a similar deposit in the testes and vesiculæ seminales. The bladder shows numerous tubercular ulcerations, especially at the summit of the organ, though there are some at the margin of the trigone near the ureter. They are superficial, circular, with ragged edges, varying in size;

[1] Tumors of the Bladder, 1881.

[4] Centralblatt für Gynäkologie, 1886, p. 464.

many have become confluent. There are some miliary points in the trigone that have not yet ulcerated. There must have been in the urine evidences of the destructive process going on in the bladder—shreds of tissue, tubercular material, bacilli, etc. But, with these, he had no symptoms to direct attention to his bladder. At least he did not complain of vesical symptoms, which may be accounted for by the fact that the vesical neck was not particularly involved. The pathological changes that accompany the tubercular infiltration are a considerable thickening of the mucous membrane and the other coats of the bladder, a veritable concentric hypertrophy, suggesting an undue functional activity on the part of the bladder, notwithstanding its absence from the history of the case.

THE PHONOGRAPH AS AN ACOUMETER, WITH THE SUGGESTION OF A STANDARD SCALE FOR TESTING THE ACUTENESS OF HEARING.[1]

By C. W. STIMSON, M.D.,

NEW YORK.

MR. PRESIDENT AND GENTLEMEN: That which I have the honor and pleasure to present to you this evening is a new method and a new application of a very modern instrument. In trespassing on your time for such a purpose one should take the greatest pains that all hypotheses are correct. Knowing my fallibility it is with considerable apprehension that I venture to address you. Trusting that you will pardon my shortcomings, I will explain the theory of my subject, endeavor to prove its practicability, and show you an instrument for its use. The title of this paper is, "The Phonograph as an Acoumeter, with the Suggestion of a Standard Scale for Testing the Acuteness of Hearing." Before proceeding to its consideration it will, I think, be proper for us to estimate the need of such a scale or instrument. There is, as you all know, at present no means by which two men, at different times and independent of each other, can invariably arrive at the same conclusion as to the acuteness of hearing in the third party.

There is no way by which we can graphically express a person's appreciation of sound. A person's own statement is our only measure of his improvement. The only universal test for the hearing is a person's ability to appreciate the tick of a watch. This is inexact and unscientific, if it has no other objections; practical aurists know of many. It was to supply a need intimated by these statements that I undertook to make a scale of sound, the method of constructing which I have the honor to explain to you. We must first briefly consider with what we have to deal. Ganot defines sound as a sensation excited in the ear. As it is a sensation we can never give it an exact mathematical value. Any measure that we may suggest must always be comparative. As with force we assume the foot-pound, so with the intensity of sound we may take a standard. Professor Tyndall tells us that we each have a lute of more than three thousand strings. No better description can be given of the compass of the ear than this. A detailed account of the minute anatomy of the ear to this audience would be superfluous. I trust that I may be pardoned, however, if I call your attention to its arrangement from a mechanical point of view. We have a cavity, the drum, approximating somewhat to a cylinder. The extremities are closed by tense membranes. Extending from one to the other is a series of levers. This arrangement is almost perfect, from the fact that its inertia is next to nothing

The Eustachian tube equalizes the internal pressure. One membrane of the drum is in contact with the labyrinth, on the surface of which is the apparatus for changing force into sensation. Corti's organ, with its three thousand strings, is brought into relationship with the system of levers by the most perfect of all contacts, a fluid medium. This organ is so tuned that it will transform every disturbance of this liquid into sensation, within certain limits. The mechanism of hearing is, then, the passage of mechanical force to a series of solid levers, from them to a liquid medium which surrounds an organ capable of recording all of its movements. From this we may say that a person's hearing is acute or dull, according to the small amount of force that his ear will conduct and register. My object has been in the scale to vary that force according to a mathematical standard. It must necessarily be only approximate. We know that the force exerted by a sound-wave varies in a regular ratio according to the distance of its source from the ear. The law reads thus, "In an unconfined uniform medium the intensity of sound is inversely as the square of the distance." Having this in mind, suppose we should cause a sonorous body, by the application of a certain force, to give forth a sound at a certain distance, twenty feet for instance. Let us then, by the use of the same body and same force, produce the sound at 4 $\frac{4\,8}{1\,0\,0}$ feet. The intensity of the first sound would be to the intensity of the second inversely as the square of the distances. In this case as one is to twenty. We might then divide the twenty feet into twenty parts according to this formula. If we should produce the sound at each of these distances we would have a series, each number of which would differ in intensity from the intensity of its neighbor by one-twentieth of the first's intensity. Should we now find that the ordinary ear could just appreciate the sound when produced at twenty feet, we might take that as the standard for normal hearing. If an individual could only hear the sound when produced at 19 $\frac{5}{1\,0}$ feet, we could express his hearing as $\frac{1\,9}{2\,0}$, providing the normal hearing was called $\frac{2\,0}{2\,0}$. These sounds differ in intensity by one-twentieth of the first sound's intensity. We could do the same with each sound of the series. For ordinary use this would be impracticable, because of the demands of the law of inverse squares. We must adapt it to ordinary surroundings. The intensity of sound can be compared, according to Tyndall, to the mechanical effects produced by a cannon-ball striking a target. The work will be proportional to the square of the velocity, or directly as the weight. The sound-waves being of the same length their intensities will be directly as their initial force. If we produce a sound by a certain force, a blow for instance, the sound-wave will be propagated a certain distance. If we increase the force it will travel a certain distance farther. At that greater distance it will have the same intensity as the first sound at the shorter distance. If heard at the same place one will be proportionately louder than the other. It was on these lines that the scale was constructed. I wished to deal with comparative intensities alone. The other qualities of sound were as near as possible kept constant; it is my intention to consider their variations in a future article. By experiment it was found that a certain sound, when produced at a certain distance and recorded on the phonograph cylinder, if reproduced could be just heard by the average untrained ear. This was taken as a unit, and the other sounds were made to vary from it in intensity by one-, two-, or three-twentieths according to the number of the stroke. The method of procedure was this: On a quiet day, I took my instrument out of doors where the surroundings fulfilled as near as possible the conditions required by the law of inverse squares. A sound was produced at a distance so great that it could just be appreciated when rendered by the phonograph. That distance was divided into twenty parts according to the above law. The sound was then produced at each of these divisions. We thus had a scale of sound, the strokes of which differed from one another by one-twentieth of the intensity of the first. I then, by experiment, found how much the force would have to be increased to make the intensity of the sound when produced at twenty feet, for instance, equal to the intensity when produced at 4 $\frac{4\,8}{1\,0\,0}$ feet. It then followed that if both were produced

[1] Read before the Society of the Alumni of Charity Hospital, April 8, 1890.

at the same distance, but with the corresponding difference in force, they would still bear the same relationship. This was repeated for each distance until the force for each intensity was determined. The sonorous body used was an ordinary hand-bell of the following dimensions: Length, 7 ctm.; diameter at mouth, 10 ctm.; at top, 4 $\frac{5}{10}$ ctm.; half-way between these, 5 $\frac{5}{10}$ ctm. The fundamental note of the bell is F natural.

My reasons for selecting this form of sounding body were mainly these: I desired to get sound alone. No advantage could accrue from having musical qualities present. Professor Helmholtz, in his most complete work on tones, states that bells have no real harmonious relations with music. Last, and perhaps the most influential, the fact that a bell gives a sharp, clear note. One is perfectly sure that he does or does not hear it. A fifty-gramme spherical weight was allowed to fall 20 ctm., and to strike the bell at a point 1 ctm. from the edge, thus producing the loudest sound of the scale. The fall was then decreased 1 ctm. for each stroke. They were all produced at a distance of ten feet from the machine. The phonograph is so common at the present time that any description would be out of place. The sounds were received into this instrument through a horn made of tin, 70 ctm. in length. Its greatest diameter is 30 ctm., its smallest 2. The cylinder was making one hundred and fifty revolutions per minute. For reproducing the scale two flexible tubes extend from the ears to a three-way stopcock; this connects by a single pipe with what is known as a 1.8-way tube. This last is of metal, its diameter 1 $\frac{8}{10}$ ctm. It extends around the machine. One end is closed, the other is attached to the reproducer. This arrangement, which, from the description, appears a little complicated, is really very simple. By its use the noise made by the instrument in action is brought to the lowest degree of prominence. The diameter of the ear-tube is 7 mm.; its length 90 ctm. A patient is informed that when the tubes are in his ears he will hear a bell strike. He is requested to count aloud the number of strokes. After placing him in position the operator notices in which direction the stopcock is turned and starts the machine. With a second pair of tubes one is able to know if the counting is done at the proper moment. If it is the right ear and twenty strokes are counted we can express the acuteness of its hearing by R. $\frac{20}{20}$. If the left ear and only ten strokes are named we write L. $\frac{10}{20}$. This, of course, can be repeated at will. The time at my disposal has allowed me to suggest only the essentials of this method. Should the subject be of sufficient interest to anyone, I shall be pleased at any time to explain the details. This instrument is like all other machines — the character of the work that it will do depends on the skill of the operator. There are very few essential points in its management; these learned, practice alone is necessary to approximate to perfect results.

68 West Fortieth Street.

How Dom Pedro Built a Hospital.—The following story of how the ex-Emperor of Brazil raised the money for a charitable institution is told on the authority of Dr. Stellwag, of Vienna: It seems that Dom Pedro longed to have a big hospital at Rio, but that he lacked the money wherewith to build it, and the wealthy people could not be induced to subscribe. Then an idea came to him, as it had to the German Emperor Joseph, a century ago. He began to grant life peerages to all persons who were willing to subscribe good round sums toward the hospital. The patents of count, viscount, and baron were not hereditary, and if the children wished to inherit their father's title they had to pay for it afresh. Brazil became thereby peopled with nobles, and the hospital was built on a grand scale. When it was completed, Dom Pedro had the following inscription placed on its gates: "Vanitas Humana Humanæ Miseriæ" ("Human Vanity to Human Misery.").

BACTERIOLOGICAL EXAMINATION AS AN AID TO CLINICAL DIAGNOSIS.[1]

By LOUIS HEITZMANN, M.D.,

NEW YORK.

On March 24, 1882, in the Physiological Society of Berlin, Robert Koch first announced his now world-famous discovery of the real cause of tuberculosis. Long before him, Villemin, in 1865, and, later on, Cohnheim had proven the infectious nature of this disease by producing artificial tuberculosis in animals by means of vaccinating with tuberculous material, but Koch was the first to show that the bacillus of tuberculosis alone would cause the disease. As is well known, this discovery, found correct by a large number of the best investigators, has revolutionized the whole science of medicine. Before this time a diagnosis of tuberculosis could, during the life of the patient, be made only from the clinical history and physical examination, and how often a wrong diagnosis was made we can readily imagine.

In the more pronounced cases the diagnosis was, of course, easy enough, but in the commencing stage it was often not possible, whereas if a correct diagnosis could have been made the patient's life might in many cases have been prolonged for a number of years by at once instituting the necessary hygienic and remedial measures. Often enough physicians erred in the opposite direction. At the present day, however, no patient, no matter what the constitutional symptoms may be, can positively be called tuberculous unless the bacilli of tuberculosis have unquestionably been found, and whenever, in a given case, these bacilli can be shown to be present, there tuberculosis most certainly exists.

The fact is, I believe, at present admitted by everyone, and all attempts to prove its non-infallibility have signally failed. It is certainly not always easy to find the bacilli, but if we only search long and thoroughly enough we will discover them in every case of tuberculosis.

This being a matter of such extreme importance, the question naturally comes up, which is the best and most certain method, especially for the general practitioner, of bringing the bacilli into view. The number of different methods that have at one time or another appeared in the medical journals is already legion, and probably each one is the best for its respective author, but if tried by one not well versed in the technic of staining the result will, as a general rule, be anything but satisfactory. We have as yet no method which will compare in usefulness with the old Koch-Ehrlich method. By those who have introduced rapid staining processes it is claimed that this method is not only tedious, but too difficult for the general practitioner, who will never succeed with it, but will succeed with their process. As a matter of fact this is by no means the case, since every method, no matter how simple it is claimed to be, must be learnt, and when the technic of it is once mastered it will give better results than any other.

One of the chief causes of failure is undoubtedly to be looked for in the coloring matter itself, which, if not well prepared, will cause all the mischief. If the coloring matter is conscientiously prepared by the examiner himself, certainly the only sure way, failures will never result.

In using the Koch Ehrlich process the first step is the preparation of a concentrated alcoholic solution of fuchsin, the coloring matter most frequently used. When once made this can be kept for a number of months and is always ready for use. It is prepared by taking one part of fuchsin in substance and adding to it five parts of absolute alcohol, which will, in a few minutes, give a solution as nearly concentrated as is necessary. The next step would be the making of the aniline water, which is made by thoroughly shaking one part of aniline oil with twenty parts of distilled water, and, after allowing to stand for a few minutes, filtering through a double layer

[1] Read before the Brooklyn Medical Microscopical Society, February 5, 1890.

of filtering-paper. If we now slowly add our alcoholic solution of fuchsin to the aniline water until a shining film appears at the top, which does not disappear on shaking, about one part of the fuchsin solution to ten of aniline water, the aniline-water fuchsin solution is ready for use. The cover-glasses having been prepared in the usual way, allowed to dry, and drawn through the flame of an alcohol lamp or a Bunsen burner three times, in order to coagulate all albuminous substances and thoroughly fix the sputum, or whatever else is to be examined, such as blood, discharge from the bowels, etc., on the cover-glass, it is dropped on the solution with specimen side downward, and either allowed to remain at the temperature of the room for from twelve to twenty-four hours, or is heated over a micro-burner for from one to two hours. In cases of great urgency, where the examination must be made quickly, we may pour the fuchsin upon the cover-glass and carefully heat it for a number of minutes over the flame, always adding fresh fuchsin as soon as it evaporates; unless absolutely necessary this should not be resorted to.

For decolorizing almost any acid can be used, but those to be preferred are nitric acid, hydrochloric acid, or sulphuric. The first can be kept in a solution of one to three parts of water, the last in a one to five solution. Muriatic acid, which is preferred by many, can be kept ready in the following solution: alcohol, five ounces; distilled water, one ounce; chemically pure hydrochloric acid, thirty drops. In any one of these acids the specimen is kept for from one half to one minute. If nitric acid has been used we drop the cover-glass in sixty per cent. alcohol for one minute, and then in absolute alcohol; if muriatic acid is used, the sixty per cent. alcohol can be dispensed with and only absolute alcohol used.

Tubercle bacilli, taking up the coloring matter with great difficulty, will also be decolorized very slowly, so that, after all the other bacteria, together with the pus-corpuscles, epithelia, and whatever else should happen to be in the specimen, have given up their color, they will yet remain perfectly colorized.

As a contrast color methylene blue is used, with which the specimen is stained for one minute, washed in water, and is now ready for examination. Methylene blue, when well made, can be kept for a very long time. The quickest way of preparing it is to add about ten drops of a concentrated alcoholic solution of methylene blue (one part of methylene blue in substance to five parts of alcohol) to two ounces of distilled water, and to this add one drop of a ten per cent. caustic potash solution. Specimens prepared in the above way will invariably show the tubercle bacilli, if any are present, with the greatest possible clearness.

As I have said before, other methods are numerous, but entirely superfluous. The fuchsin can be prepared with carbolic acid, or boric acid, or salicylic acid instead of aniline water, and such solutions keep, which is the only advantage over the original method; but, considering that we can prepare a fresh aniline-water solution in a few minutes, are hardly worth using. One method, which has been praised a good deal, is a modification of Ziehl-Nielsen's carbolic-acid fuchsin method, the principle of which consists in using a sulphuric-acid methylene-blue solution, where the contrast color and the decolorizing agent are used together. Though this method appears to be extremely simple, it is certainly more difficult for the general practitioner to make a good specimen with it than with the previous method.

If we examine a large number of different sputa of persons *suspected* of having tuberculosis we will frequently be able to corroborate the physicial diagnosis, but perhaps just as frequently not find bacilli of tuberculosis in spite of the most careful examination. In no suspected case should we be positive as to the absence of bacilli until we have most thoroughly examined at least six well-prepared cover-glasses, and occasionally it may become necessary to examine sputa of the same patient three or four or even more times. Supposing, now, that we have become convinced of the non-presence of tubercle bacilli, is it possible for us to make any other diagnosis from the bacteriological examination alone, without at the same time knowing any of the clinical features of the case? Bacteriology has unfortunately not yet advanced so far that we can in every case make a positive diagnosis where tuberculosis can be excluded; but we are certainly able, in a number of cases, to assist the clinician, and sometimes even to tell him with pretty great certainty what the trouble is. In most of the cases where sputa are examined it is, of course, not possible to set about making any cultures, and for that reason we can only give a guarded opinion, but even that is often sufficient for the clinician.

In the first place, what will we expect to find in every sputum where an inflammatory process is going on, no matter what that process is? We will find pus-corpuscles in greater or smaller numbers; epithelia from the respiratory and oral tracts, ranging in size from those about one-third larger than the pus-corpuscles, which are probably derived from the lungs, to the very large ones from the mouth; staphylococci and streptococci pyogenes, the number of which varies with the number of pus-corpuscles and the intensity of the process; very often some sarcinæ, and occasionally yeast and the bacillus subtilis, which latter are contaminations from the air.

As regards the staphylococci and streptococci, which are the more numerous, and is their relative number always the same? That these cocci are present almost everywhere where there is pus is denied by no one, though the axiom which a number of years ago was put up by a number of investigators, "No suppuration without micro-organisms," is probably not strictly correct. At any rate this is yet an open question. The staphylococcus is undoubtedly the most frequent organism of suppuration, and is present in the greatest number of cases where there are any cocci at all. The streptococcus pyogenes has been found in about sixty per cent. of all the examined cases. It is especially frequent in such inflammations which concentrate themselves in the lymph-channels. As a general rule it does not produce such quick suppuration and destruction of tissue as does the staphylococcus, but it may penetrate the tissues very far before it destroys them. Rosenbach, to whom our knowledge of the pyogenic microbes is mostly due, has already called attention to this fact, which was corroborated by all later observers. The streptococcus will therefore be more frequently found in phlegmons and diffuse suppurations of serous cavities, but very rarely or not at all in the pustular processes, such as furuncles and carbuncles, which, as it seems, are almost exclusively caused by the staphylococci.

So much for the general inflammatory and suppurative processes, but how is it in the sputa examined? Here we will almost invariably find *both* staphylococci and streptococci, but by no means in the same proportion. From a large number of sputa which I have examined I think I can say that the more streptococci are present in a given case, and the less staphylococci, the severer the inflammatory process will be, and in abscesses and gangrene, which of course are very rare, we will find almost nothing but streptococci. That this is invariably the case I am not yet prepared to say, but in the larger number of specimens it certainly holds good and is very often an extremely important factor in the making of a diagnosis. The following example will serve to illustrate this:

About two years ago Dr. B—— brought to me a sputum, with the request of examining for tubercle bacilli, the diagnosis of tuberculosis having been made by one of our foremost diagnosticians. As I afterward learned, the patient was a man, aged fifty-one, who was perfectly well up to the time of his last illness, which commenced with chills and severe headache. On the second day cough began, accompanied by slight expectoration. Chills and night-sweats continued at irregular intervals until death. At the time of the examination, however, nothing was

known by me about the case. Of this sputum cover-glasses were made in the usual manner, and they were stained with the Koch-Ehrlich method. Very careful examination failed to reveal any tubercle bacilli, but there were present a large number of pus-corpuscles, epithelia from the respiratory tract, especially small ones, probably derived from the lungs, an enormous amount of streptococci, comparatively few staphylococci, quite a good deal of the micrococcus tetragenus and small bacilli, rounded off at the ends, which I had every reason to believe were samples of the bacillus pyogenes fœtidus, first cultivated by Passet from an abscess. Of the latter I was still firmer convinced on the following day, when the sputum had developed a putrid odor, not present when it was first received. From all these features I made the probable diagnosis of an abscess of the lung. One week later the sputum was again sent to me for examination, when all the above features, but especially the streptococci, were present in a much more marked degree than on the preceding examination. On this occasion I again made the diagnosis of abscess, perhaps even gangrene, of the lungs, and reported the patient to be much worse than the previous week. Two days later he died, and the post-mortem examination showed that there was a large abscess at the apex of the right lung.

In another case the same features were present and the same diagnosis made, afterward corroborated by the clinical character, but no post-mortem examination was here allowed.

In the first case, then, the earliest intimation as to the probable diagnosis was given from a bacteriological examination, without the knowledge of any of the clinical features. As soon as the diagnosis was intimated, the clinician admitted that he himself considered it to be more probable than the diagnosis of acute phthisis previously made.

Quite frequently sputa suspected of being tuberculous are brought for examination where we are pretty safe to say that there is severe bronchitis but no tuberculosis.

Besides all the bacteria which have so far been mentioned, there are still others that are occasionally found in sputa coming from patients where the clinical diagnostician has not made a positive diagnosis, but thinks that there may be a commencing tuberculosis. The most important among these is the pneumococcus or pneumo bacillus. In 1883 Friedländer first called attention to the fact that in pneumonic patients we almost invariably discover peculiar oval cells, which are sometimes pronounced micrococci, at others short bacilli with rounded-off ends. They are very often found in groups of two, four, or even six, surrounded by a sort of capsule; this latter is not invariably present, but in almost all specimens taken from the animal body, never in those made from cultures. That this bacilli is by no means the sole cause of pneumonia is certain, also that we may occasionally find bacilli exactly resembling them in perfectly normal sputum.

Several years after Friedländer's discovery A. Fränkel described a bacillus or coccus very similar to the above, but undoubtedly different from it, as the producer of pneumonia. The main differences between the two are that Fränkel's is shorter, that there are not as many grouped together, and especially that it retains its color when subjected to Gram's method, whereas Friedländer's bacillus becomes discolored. Besides these two, a number of other cocci and bacilli have at different times been described as producing pneumonia, but at the present day it is admitted that in the larger number of cases of acute croupous pneumonia either Friedländer or Fränkel's cocci will be present. This knowledge will not infrequently aid in making a diagnosis. In quite a number of cases of sputa examined, my probable diagnosis of pneumonia has afterward been found correct; in most of these tuberculosis was at first suspected. Should the number of staphylococci and streptococci present together with the pneumococci be very large, we may suspect pleuro-pneumonia.

It has been believed by some that the same organisms will sometimes be found in catarrhal pneumonia, and I have a number of times been able to prove this assertion. Not long ago a sputum was sent to be examined for tubercle bacilli. The physician sending it was tolerably certain, from all the clinical features, among which was rapid emaciation and continual night-sweats, of it being a case of tuberculosis, but he wished to become positive by having a microscopical examination made. The diagnosis of pneumonia, of course it was impossible to say whether catarrhal or croupous, he would at first not consider correct; but on meeting him about a week later, he informed me that now there was no doubt of the case being one of a catarrhal pneumonia, and that the patient was rapidly improving.

Such cases are not by any means rare, and tend to show that though bacteriology is still in its very infancy, and as yet a very unsettled study, we can, by a little practice, often greatly benefit the practitioner, even if we tell him only that such a diagnosis is probably the correct one. That cultures would in many cases enable us to speak with more positiveness is undoubtedly true and not only is the time for making them too limited in most of the cases where a sputum examination is wanted, but, as a general rule, it is not at all necessary, since positive diagnoses are not expected where tuberculosis can be excluded. The time will undoubtedly come when we will be able to do much more than we can now, but at present let us be satisfied with the little that has so far been accomplished. The more that examinations of sputum will be carried on, the more accurate diagnoses will we be able to make. That a great deal also depends upon our being able to correctly diagnose the epithelia found, is as certain as it is in making correct diagnoses of genito-urinary troubles by means of the microscopical examination of urine. Carl Heitzmann has for years claimed to be able to make positive diagnoses of such troubles from simple microscopical examinations of urine, without knowing anything at all about the clinical symptoms of the case, and he has time and again proven his assertions to be correct. Unfortunately, the possibility of making such diagnoses is still denied by most other observers in spite of the many proofs which have been brought forward to substantiate the claim made. Although so far we have not been able to diagnose epithelia from the respiratory tract with absolute certainty, there is no reason why, before long, we should not be able to do so.

So far I have concerned myself with the examination of sputa only, and here the finding of tubercle bacilli, when any are present, is comparatively easy. This is not the case, however, with other excretions, such as mucus from the bowels or urine. The examination of such specimens has to be conducted with much greater care, and a good deal of patience is required in carrying out such investigations; but if we only have the perseverance we will be rewarded. In such specimens, when they come from tubercular patients, we must not expect to find a large number of bacilli, but will have to rest satisfied if a few undoubted ones are found. These will be sufficient for a diagnosis.

The examination of blood also is very tedious, but in this case, too, we can make a positive diagnosis. Some time ago a handkerchief was brought to me which contained a small clot of blood, with the request of examining this blood for tubercle bacilli. After having soaked it in distilled water, cover-glass specimens were made, and the examination, though it had to be carried on for a long time, was rewarded by the discovery of a small number of tubercle bacilli, which left not the slightest doubt as to their nature. Up to the time of the examination characteristic symptoms of tuberculosis had not developed in this patient, but commenced not very long after.

The next part of my subject is the bacteriological examination of urethral or vaginal discharges. This is a matter of no less importance than the previous one. The principal question to determine here is, whether we are

able in every single case to pronounce a given discharge as gonorrhœal or non-gonorrhœal. Let us take for example one of those not rare cases where a man who has had gonorrhœa many years ago, and has long since considered himself cured, becomes engaged to be married. Without any apparent cause, except perhaps the sexual excitement under which he labors when in the company of his intended, he one day notices a slight discharge from his urethra, which, instead of diminishing, becomes rather worse, until he gets frightened, and now wants his physician to tell him whether it is his old gonorrhœa, which has remained latent and broken out again, or whether it is only a harmless, non-specific urethritis. That this question is of the greatest importance, we can readily imagine. Is it possible to make such a diagnosis? It undoubtedly is, though not always easy in some such cases; however, even one examination may be sufficient to make a positive diagnosis of gonorrhœa, and such a patient should naturally not be allowed to marry.

In the year 1879 A. Neisser, of Breslau, for the first time described cocci, afterward called gonococci, as invariably present in all gonorrhœal discharges, and in these only, and which he therefore regarded as the only true cause of gonorrhœa. These cocci appear almost invariably in the form of diplococci, and have a characteristic arrangement. Each coccus is divided into two by a light space, and the adjacent sides are usually somewhat flattened, thus having the so-called biscuit form. Single cocci will only exceptionally be found. These cocci lie in irregular masses, either entirely within or entirely without the pus-corpuscles and epithelia, but never halfway within and half-way without. They never lie in the nucleus, which invariably remains free, no matter how crowded the pus-corpuscle may be. This arrangement Neisser believed to be entirely characteristic, never being found in other than gonococci. His assertion was investigated by large numbers of experimenters, and a great many articles for and against the theory made their appearance. By some, especially Lustgarten and Mannaberg, it was claimed that cocci which could in nowise be differentiated from gonococci were occasionally present in the perfectly healthy urethral mucous membrane, not only in the fossa navicularis, but also in the deeper portions; that slight differences exist nevertheless is, however, quite certain. These cocci Lustgarten and Mannaberg claimed were also found within the cells, exactly in the same way as gonococci. That they could only have found them in epithelia, and not in pus-corpuscles, is quite evident, since pus-corpuscles are, of course, not present in the healthy urethra. When Neisser and, after him, Bumm described the intracellular arrangement as characteristic of gonococci, they always meant pus-cells and not epithelial cells, since all other kinds of cocci and bacilli may also arrange themselves within epithelia; but diplococci were very rarely found within the cells, and where such was the case the size usually excluded their being gonococci.

The questions to be answered, then, will be, first, Is the gonococcus described by Neisser really the virus of gonorrhœa? Second, Can gonococci, when found in a given case, invariably be considered as diagnostic evidence of the presence of gonorrhœa and sufficient for the differential diagnosis between a specific and a non-specific urethritis? A very large number of examinations by many different observers have shown that gonococci are constantly present in all diseases of the mucous membrane which run the clinical course of a gonorrhœa, so much so that wherever gonococci are positively found, gonorrhœa can with certainty be diagnosticated. Mechanical and chemical irritants of the urethral mucous membrane, which may also cause suppurative discharges, will never be attended by gonococci. Other cocci may sometimes also cause a urethritis, but such cases are clinically different from a true gonorrhœa.

In cases of undoubted acute gonorrhœa, especially when a number of days old, the specimen will, upon examination, be seen to be filled with gonococci, and other microorganisms will in such cases rarely be found. After having made our cover-glass specimens in the usual manner, we simply color for half a minute with a watery solution of fuchsin or gentian violet, which will be all that is necessary in such a case. All, or almost all the cocci present will be seen to have the characteristic appearance of gonococci, being grouped within the pus corpuscles, the nucleus, however, remaining free. Occasionally, even in such acute cases, other cocci, such as staphylococc and streptococci—easily distinguishable by their arrangement — are present, especially in such cases where we do not have a simple gonorrhœa, but at the same time some other inflammation, such as an acute prostatitis or a peri-urethral abscess.

For purposes of differential diagnosis we must resort to another method, in order to satisfy ourselves, with absolute certainty, whether cocci, which to the eye appear to be gonococci, really are such. Roux was the first to call attention to the fact that gonococci lose their coloring matter when subjected to Gram's method, whereas other cocci keep their color. This has been found to be correct in almost all cases examined, so that at present we can consider it one of the most important points for differential diagnosis. Gram's method consists in first coloring with an aniline-water gentian-violet solution, made by mixing one part of gentian violet in subs'ance with one hundred parts of aniline water, and then subjecting the specimen to an iodine iodide of potash solution—iodine, one part; iodide of potash, two parts; distilled water, three hundred parts. After having drawn the cover-glass through the flame three times, we allow it to float on the aniline-water gentian-violet solution for from twenty to thirty minutes; from there we transfer it directly into the iodine iodide of potash solution, where we leave it about five minutes. Now it is placed in absolute alcohol, where it is kept until entirely discolored, that is, until the alcohol dropping off the cover-glass does not show any violet tint; the time for this will vary, but will be from three to five minutes. If we wish to obtain good specimens, both the iodine iodide of potash solution and the alcohol should be changed a number of times, and each fresh specimen be subjected to a fresh solution, otherwise precipitates will remain in the specimen, and may cause serious annoyance. After the specimen is entirely decolorized it is washed in distilled water and may at once be examined. The only things which have remained colored after this procedure are bacilli and cocci other than gonococci which happen to be in the specimens.

It will be much more convenient, however, to recolor the specimen with some contrast color. Here we are confronted with the difficulty that by recoloring such specimens mistakes can easily be made, in that an overstaining of such bacteria which have retained their color after treatment with the iodine iodide of potash can quickly take place with the second color. Especially fuchsin and the solutions of safranin, which Roux originally recommended, overcolor so quickly that we cannot allow the coloring matter to act longer than a few seconds, even if the solution is as weak as possible. If such overstaining has once taken place, even the most experienced observer can only with great difficulty find a difference in color between those cocci which have lost their staining when subjected to Gram's method, and those which have kept it, and then it can easily be imagined that a decoloring has taken place where such is not the case.

The best color for this purpose, certainly the one which is least liable to overstain, is Bismarkbraun vesuvin, which can even be allowed to act for from one to two minutes. The solution must not be an alcoholic one, but a from one to two per cent. watery solution will fulfil all purposes. It is true that vesuvin also has its disadvantages, among which the most important is that after coloring with it the specimen is often not entirely clear, and if we examine such a specimen for some time the eye easily becomes tired. Of all contrast colors it is, however, undoubtedly the best.

In specimens prepared in the above manner the pus corpuscles, epithelia, and gonococci will be stained brown, whereas all the other bacteria have a blue, or, at least, a very dark color. The contrast between gonococci and the other cocci will be sufficiently marked in every case, so as to enable us at once to diagnosticate between them. Out of a very large number of cases examined by different observers, only four per cent. showed a small number of cocci not gonococci, which lost their color when subjected to Gram's method, and these were so entirely different from gonococci that they could not be mistaken. All intracellular cocci, without exception, which have lost their color, can undoubtedly be pronounced as being gonococci. With only a little care in the preparation and examination of such specimens, mistakes should not occur. How often have cases of acute urethritis been examined where the patient at first positively denied all possibility of infection by sexual intercourse, but where, after a microscopical examination, he reluctantly admitted that, after all, this was the source! Cases in which a slight urethritis is caused in married life from too frequent indulgence are not rare, but never have I been able to find gonococci in them. These cases will always run a shorter and a milder course than true gonorrhœa.

One very interesting case has just come under my observation. The patient, a man over fifty years of age, who has had a number of gonorrhœas in his life, but the last many years ago, and has for a long time been a healthy man, married, a number of months ago, a woman somewhat advanced in years, but still virgin. She had a very slight vaginal discharge, but was otherwise well. When he first tried to have sexual intercourse with her he was utterly unable to rupture the hymen, and therefore had to desist. The next morning he noticed a discharge from the urethra, which grew worse, and lasted a number of weeks. He thought that he had true gonorrhœa. Some time after his first attempt he again tried, again failed to penetrate, and again had an attack of urethritis. On the third trial urethritis once more resulted, and this time he brought a little of the vaginal discharge for examination. Cover-glass specimens having been made from the discharge and the same put under the microscope, it was found to contain some epithelia and a few mucous corpuscles completely filled with cocci, and free cocci in great abundance. These cocci were found almost invariably in groups of two, exactly resembling the gonococci, but did not have the typical intracellular arrangement. Upon being subjected to Gram's method they retained their color. I do not doubt that here we had nothing but the micrococcus subflavus Bumm, which, though harmless to the woman, would invariably set up a urethritis in her husband. The patient was of course told that he had no gonorrhœa, but that he should not attempt to have any more intercourse with his wife until examination of the vaginal discharge proved the absence of the coccus.

Cases of mixed infection, though not numerous, are still sufficiently frequent to warrant some attention. In a case of this kind, examined some time ago, the diagnosis of severe prostatitis, possibly abscess of the prostate, together with gonorrhœa, was made from the microscopical examination alone, without knowing anything of the history. Here, of course, the knowledge of the epithelia also comes into play. The history, which I afterward learnt, is as follows: The patient was a medical student, twenty years of age, who, just to learn the feeling experienced by the passing of a sound, passed a not very clean instrument on himself; though it caused considerable pain, he persisted until he had succeeded. The same night he had a severe chill and much pain, especially in the prostatic region. On the following evening he had sexual intercourse, as he averred for the first time in his life. The day after he felt so bad and broken down that he consulted a physician, who not being positive what to make of the case, simply advised rest in the recumbent position and applications of ice. On the fifth day a very purulent discharge was present, some of which was brought to me for examination. The diagnosis was clear enough, and there was not the remotest doubt that here we had to deal with a case of mixed infection. Both staphylococci and gonococci were present in very large numbers, though perhaps the former predominated. The epithelia from the prostate were very abundant, beside these, of course, epithelia from the urethra, which will be found in every case of gonorrhœa.

In all chronic cases of urethral discharge, where a diagnosis cannot be made from the clinical symptoms, bacteriological examination in the above manner should be resorted to, and will almost invariably sooner or later clear up the case. In such instances we will be pretty sure to find other cocci, very often also bacilli, but if the discharge is gonorrhœal, gonococci, though sometimes in rather small numbers, will surely be present. Here again one examination will, in a suspected case, not be sufficient; if gonococci are found at the first examination, there remains no doubt as to the diagnosis; if not, a number of examinations must be made. In one case examined the patient had his last attack of gonorrhœa eight years ago; this attack lasted a very long time, but finally stopped and he considered himself cured. He became engaged to get married, and one morning, on waking up, noticed a slight discharge from the urethra, which, instead of becoming better, grew somewhat worse. Treatment was instituted and an examination of the discharge requested. The first examination revealed a prostatitis, but no gonococci could be found; a second examination, made after treatment had been stopped for some time, revealed gonococci, but, on account of the gravity of the case, the discharge was again examined a week later, when no doubt remained as to it being due to gonorrhœa. The patient was advised not to marry at present, and soon after broke off his engagement.

In conclusion I can only repeat that bacteriological examinations should in all doubtful cases be resorted to, and will frequently either clear up the case completely, or at any rate help toward the making of a correct diagnosis by the clinician.

Progress of Medical Science.

The Urine in Pernicious Anæmia.—More evidence in support of the view of pernicious anæmia being a hæmolytic process, initiated probably by some ferment in the gastro-intestinal tract, and evinced, therefore, most markedly in the portal blood—a view well worked out by Dr. W. Hunter, of Cambridge—has been lately adduced by this observer in a series of papers contributed to *The Practitioner*. The subject-matter of his contributions consists in observations on the excretion of pathological urobilin, of blood-pigment, and of iron. He made careful analysis of the urine in a typical case of the disease, and draws especial attention to the exceedingly high color of this fluid, although the average specific gravity was never above 1.016. Indeed, in the later stages, when the quantity passed was greatest and the specific gravity lowest, this deep coloration was most marked. Such a condition cannot fail to arrest attention, for it is in marked contrast to the character of the urine in other forms of anæmia. The fact, too, has been noted by other observers. Bile-pigments were not the cause of the coloration, but spectroscopic examination proved the presence of pathological urobilin, which MacMunn has shown to be distinct from the urobilin of normal healthy urine, and its occurrence was found to be associated with an excessive elimination of bile into the intestine. This increased production of bile-pigments indicated an increased disintegration in the liver of hæmoglobin; but Dr. Hunter remarks that not all the "pathological urobilin" could have had this hepatic origin, since at death, when the urine still remained of high color, there was no excess of bile

in the duodenum or small intestine. The probability is that other organs also yielded this product of blood destruction, and that some of the pigment in the urine was due to increased absorption from the intestine. Besides this, however, a study of the minute appearances of the kidney in this disease shows an accumulation of pigment-granules in the epithelium of the convoluted tubules during life, while tube casts and cells containing such granules may be detected, especially at certain periods of exacerbation of the disease, when it might well be inferred that the blood destruction was more intense. These facts led to an inquiry as to the excretion of iron in the urine in health and disease. Dr. Hunter estimates that the average daily excretion of iron is from 3 to 5 milligrammes. It is remarkable that the administration of iron by the mouth very slightly, if at all, increased the amount of iron excreted. Dr. Hunter found, in one observation in health, the quantity of iron excreted in the urine was 5.65 milligrammes; in one case of chlorosis, 1.71 milligramme; in another, 1.96 milligramme; and in a third, 1.61 milligramme, considerably lower than the average, but consonant with the diminished richness of the blood in hæmoglobin characteristic of this affection. In a case of pernicious anæmia, however, the amount of iron in the urine passed about three weeks before death was no less than 32.26 milligrammes, twelve days later 6.52 milligrammes, and two days before death only 1.00 milligramme. It is just ten years ago that Dr. Finny reported a case of pernicious anæmia in which Dr. Emerson Reynolds found a considerable quantity of iron in the urine; but otherwise the observations on this head are comparatively few. Still, such as they are, they harmonize completely with the hæmolytic theory, and are all the more striking when it is remembered how very deficient the blood is in coloring matter during the closing stages of the disease. Dr. Hunter thinks that these three conditions of the urinary pigments—viz., the presence of pathological urobilin, the presence of granules of blood-pigment as detected by the microscopical examination of the urine, and an increased excretion of iron—are of importance not only from the pathological stand-point, but also diagnostically. Not, indeed, that such changes are always to be noted in pernicious anæmia, but in periods of its course, periods when the disease is undergoing exacerbation, and which the examination of the blood, as well as the general condition of the patient, prove to be periods of increasing hæmolysis. For pernicious anæmia is seldom—in its earlier stages at least—regularly progressive. Many physicians have had experience of cases in which there was amelioration for a time, followed by a subsequent rapid relapse of the weakness and anæmia; and the irregular pyrexia so characteristic of the affection also seems to denote this liability to exacerbation. The observations he has made regarding urobilin likewise tend to support Dr. Hunter's contention of the blood destruction being initiated in the portal system, and we look forward to his promised further investigations into the nature of the gastro-intestinal changes which he believes to be the *fons et origo mali*, and into the measures to be taken to combat these changes. For if his view be the true one, it is hopeless to expect any other permanently successful method of treating pernicious anæmia than by attacking the disease at its source.—*The Lancet.*

Treatment of Chlorosis by Rectal Injections of Defibrinated Blood.—In a recent thesis Dr. Antiq relates the results obtained by a novel method of treating chlorosis suggested long since by Teissier. The material employed is the blood of oxen, duly defibrinated. About five ounces of this is injected *per rectum* twice a day for a week. The treatment is discontinued at the end of that period for a week, and then recommenced. Care should be taken to warm the blood over a water-bath before injecting, and the patient should be directed to retain it as long as possible, any colicky symptoms being overcome by the addition of a few drops of laudanum. According to the author, this treatment is more rapidly and certainly successful than any other at present resorted to. The proportion of red corpuscles in the blood promptly increases, and the mucous surfaces regain their normal color. He attributes the rapid improvement that takes place to the fact that the employment of defibrinated blood fulfils three indications—1, restitution of the iron; 2, restitution of oxygen; and 3, restitution of the salts of potash and the chlorides. Dr. Huchard, commenting thereupon, mentions that, in a case of his own, he had succeeded in overcoming an anæmia which had resisted all medication.—*Revue Gén. de Clinique et de Thérapeutique.*

Observations on Rheumatoid Arthritis.—Dr. Kasanli has published an account of some microscopical observations he has made on the morbid changes of the various structures of the knee-joint which accompany old age, with the view of comparing these changes with those occurring in rheumatoid arthritis, or arthritis deformans, as this affection is frequently called. The morbid changes found in the synovial membrane were most marked in the adventitia, and consisted in hyperplasia of the cellular elements and the development of connective tissue in the adventitia, together with thickening of the walls of the capillaries lying beneath the intima synovialis, also in a varicose enlargement of the capillaries, in separation of adipose tissue in the synovial membrane, and in splitting of the adventitia into fibres. In the cartilages the cellular elements were found to be undergoing fatty degeneration, and the interstitial substance to have broken up into fibres, and to have become infiltrated with certain saline matters. In the spongy portion of the epiphysis of the femur the trabeculæ had become very thin, and cavities had been formed by the absorption of the osseous substance of lamellæ, into which the bone near the cartilaginous covering had split up. In the medulla of the bone there was a marked deficiency of medullary elements, the small vessels were affected by a varicose enlargement, and their walls were thickened. These changes, which occur normally in the knee-joint in old persons, are, according to Dr. Kasanli, very similar to those found in rheumatoid arthritis.—*The Lancet.*

Pneumonic Infection in Utero.—The recognition of the infective nature of pneumonia by the bacteriologist has seldom received so marked an illustration as in a contribution by Dr. Levy, of Strassburg, upon the apparent transmission of this disease in utero. The case is related as a "typical example of infection of the fœtus in utero with Fränkel's diplococcus." The child was born at full term the day before its mother died from pleuro-pneumonia. Three days later the infant itself succumbed to a "hemorrhagic, catarrhal, lobular, and lobar pneumonia." The diplococcus was found in the pleuritic exudation of the first case, and mice inoculated with this fluid died with all the recognized signs of "pneumonococcus sepsis," presenting fibrinous pleurisy and pericarditis, splenic swelling, and diplococci in the blood and viscera. The infant's lung yielded the same microbe. That neither the inhalation of foreign bodies nor septic infection caused its pneumonia, was proved by microscopical examination. Moreover, it is stated that râles were heard in the infant's chest within seven hours of its birth, and that many cocci were found in its blood. It is held that it could not have received the disease except through the maternal blood, so that the argument involves not only the infectivity of pneumonia, but its transmissibility to the fœtus. To this one might add, as a possibility not to be disregarded, the effect of chill on the new-born infant, upon which the history is silent; but according to the new teaching, if chill had operated it would have been as a predisposing, and not as an efficient, cause. It is stated that pneumonococci have been found in the fœtal blood, but that for pneumonia to occur the infant must have breathed. Is not this a weak link in the chain of etiological reasoning?—*The Lancet.*

Pathogenic Sporozoa.—The Sporozoa are unicellular organisms, wholly parasitic, and distinguishable into the four orders, Gregarinidia, Sarcosporidia, Myxosporidia, and Microsporidia. The Gregarinidia are well known for their parasitism upon insects. For the most part unicellular, they multiply by conjugation, whereby the two united cells are transformed into a single cyst, in which the protoplasm becomes segmented and finally converted into a vast number of ovoid spores, or "pseudonavicellæ," each spore being encased in a resistant shell. The spore itself gives rise to two or more "germs," which are capable of some activity, and have been observed to penetrate into the intestinal epithelium of the insect which has taken up the spores. We have here on a small scale the alternation between a free and a stationary existence which marks so many of the higher parasites. The Sarcosporidia are usually found in the muscular tissues of vertebrates, and although it has not been proved that their presence gives rise to any symptoms, it is quite possible that some cases of "polymyositis" described by Unverricht may be due to an invasion of the parasite. In the muscle they are contained in tubes, as globular cysts, of which the most developed enclose "germs" similar to those forming in the "spores" of gregarines. The Myxosporidia occur on the skin and mucous membranes of aquatic vertebrata; their spores are furnished with projectile threads. The Microsporidia have spores so small as to have been mistaken for bacteria. They invade the tissues of insects, and to them is owing the silkworm disease pebrine, which has caused such ravages in silk culture. The best known forms of this class which occur as parasites in the human subject are the coccidia, which are so common in the liver of the rabbit. In man they have been met with in that and other organs, and doubtless would be more often found if their presence were generally recognized. Professor Wright records how Steinhaus has described one form as invading the nuclei of the intestinal epithelium of the salamander, and Podwyssozki another which invades the nuclei of the cells of the human liver, causing their destruction and inducing a kind of cirrhosis. It is here that we touch upon the potential importance of these lowly parasites. That they attack the cells and their nuclei, and thus may lead to important lesions of nutrition, is indeed a fact of wide bearing. Hence it is not surprising to find the singular affection "molluscum contagiosum" referred to their agency, while an explanation is afforded of the peculiar "molluscum corpuscle" which has hitherto been hard to find. The coccidia are described as invading the cells of the rete mucosum, replacing the cell protoplasm and sporulating within the cell, forming six to ten refractile bodies, which by mutual pressure convert the remains of the invaded cell around the coccidium cyst into the "molluscum corpuscle." Still more interesting are the observations of Darier, who has demonstrated that acne cornea is really a "psorospermosis follicularis," and has further declared that Paget's disease of the nipple is characterized by the presence of coccidia in the deeper cell-layers. A like interpretation has been placed upon the familiar contents of the cell-nests of epithelioma, and Dr. Maccallum of the Toronto Histological Department showed Professor Wright four years ago "sporulating cysts in epithelioma, and suggested the parasitic origin of the disease." Of course, it may be said that there has yet been advanced but little proof that the bodies described in these cutaneous affections, and in cancer, are really what they are claimed to be, and not, as they have hitherto been regarded, merely the products of degenerative change in the cells. If it were possible to cultivate the sporozoa, as can be done with vegetable parasites, the question might soon be settled. However, the more that is made out concerning the behavior of the gregarine in the insect, and its allies in other and higher forms of host, the more strong will be the argument derived from analogy. It has thus been shown that these parasites can and do attack the cell-elements, and hence it is not difficult to believe that even in the perverted cell changes of cancer they may take a part. The search for a bacillary parasite in cancer has proved delusive. Is it altogether visionary to anticipate that there may one day be found good evidence of a parasite of the class we are considering being at the root of this baffling group of diseases? Attention must be more and more given to cell parasitism and its effects. The remarkable researches upon the blood in malaria by many observers have shown that the blood itself may be the seat of amœboid or infusorial forms of animal life, which are very probably directly related to the disease in which they occur. Only the other day no less an authority than Professor Klebs described similar forms in the blood of influenza subjects. In point of fact, pathology is now being dominated by parasitism, and disease is becoming more and more the resultant of an internecine warfare between the minutest forms of life and the constituent cells of the higher organism. In the end, of course, the dead tissues become the seat of the fermentative action of bacteria. During life it depends largely on the inherent vitality of the cells whether they do not succumb to the living forces that so constantly beset them. There is, however, a vast field still open for research in this direction, and many a cherished theory may yet have to fall before the stern facts of science, whose only aim is the setting forth of truth.—*The Lancet.*

Tubercular Peritonitis.—From a study of this subject, based on personal experience, Dr. William Osler has formulated the following conclusions: 1. Tubercular peritonitis is often a latent affection, localized in the peritoneum, which may even run its course without inducing special symptoms. 2. As in other local tubercular processes, there is in this a natural tendency to healing, which takes place more frequently than has hitherto been supposed. 3. Statistical evidence shows laparotomy to be in many cases a palliative, and in a certain number a curative, measure.—*The Johns Hopkins Hospital Reports*, February, 1890.

Embryocardia.—In a recent communication read before the French Société Médicale des Hôpitaux, Dr. Huchard insists upon the symptomatic value of the presence of the "fœtal rhythm" of the heart, to which he has given the name of embryocardia. It is generally indicative of approaching dissolution, and consists of: 1, An acceleration of the heart-beat (tachycardia); 2, an equalization—*i.e.*, a tendency to an equal duration—of both pauses; 3, a similarity in the tone and intensity of both sounds. It differs materially both in nature and significance from simple tachycardia, and there is no material relationship between the two. The anatomical causes of this condition are: 1, More or less advanced degeneration of the myocardium; and, 2, extreme enfeeblement of arterial tension. These two conditions are especially to be noted in typhoid fever; hence the frequency with which embryocardia is remarked in the course of severe typhoid, but it is also met with in scarlatina, pneumonia, diphtheria, and generally in cachexia from any cause, and at the later stages of asystole. It is generally the forerunner of collapse, and is always a sign of grave import. The treatment of this condition comprises two indications; 1, to increase the contractile force of the heart; and, 2, to increase arterial tension. Digitalis, however, is rather injurious than otherwise, and the best means of increasing the strength of the heart-beat is by the subcutaneous injection of caffein, while arterial tension is best augmented by hypodermic injections of ergotin or ergotinine.—*The London Medical Recorder.*

Benzin for the Removal of Smegma.—For cleaning off smegma, and greasy applications used in treating balanitis and similar conditions, there is nothing equal to benzin. The application is painless and it cleans the surface without rubbing. It also seems to have a curative effect upon ulcerations.—*Canada Medical Record.*

MEDICAL RECORD:

THE DIAGNOSIS OF CANCER OF THE STOMACH.

THE diagnosis of gastric cancer is often extremely difficult. In just the same measure with its difficulty, however, comes its importance to the patient; and it is not surprising that the ingenuity and acuteness of medical men has been bestowed most actively upon this subject.

The ordinary diagnostic indications are familiar to our readers; the age of the patient, the physiognomy, the pain, the vomiting, the tumor felt on palpation, etc. We have several times called attention to the occasional value, in a negative way at least, of tests of the gastric juice for hydrochloric acid. Dr. G. Lyon (*Gazette des Hôpitaux*) has recently reviewed quite thoroughly the other alleged helps to diagnosis, furnished by examinations of the urine and the blood.

One may find, he says, in cancer of the stomach diminution in urea and in phosphates, a slight amount of albuminuria, or of peptonuria, or glycosuria, indican, and urobilin.

Rommelaere first called attention to the diminution of urea in cancer, and asserted that when the daily amount fell below twelve grammes, one ought to suspect cancer. M. Kirmisson has stated in support of this opinion that persons suffering from cancer anywhere, do not, as a rule, excrete more than ten grammes of urea daily. MM. Deschamps, Dujardin-Beaumetz, and Robin have all, however, contradicted Rommelaere's statements, and all that can be said probably is that in cancerous patients there is usually a diminished amount of urea excreted.

The same author, Rommelaere, states that in cancer there is a diminution of phosphates, which is not dependent upon diet. Jaccoud, in confirmation, reports a case in which the daily amount of phosphoric acid was 1.34 to 1.36 gramme, or about half the normal.

One sometimes finds traces of albumin in the last stages of cancer, but its presence is of no diagnostic significance.

If sugar is found in the urine, however, in connection with symptoms of cancer of the pylorus, it may be assumed that the pancreas has become involved. Indican is often found in the urine of the cancerous as in other diseases, and Jaksch has observed the "Burgundy-red" color obtained by adding a very dilute solution of the tincture of chloride of iron, a coloration attributed to the presence of acetone.

Much more significant is the presence of peptone in the urine, this was found regularly by Maixner in twelve cases of gastric cancer. Pacanowski, also, found it uniformly. Whether it may not be equally frequent in gastric ulcer is not stated.

M Hayem, in his work on the pathology of the blood, has made some observations as to its change in persons suffering from cancer. He notes alterations in the number and form of the red and white corpuscles, morphological changes in the hæmatoblasts, and diminution in the chlorides of the blood and in the hæmaglobin. The red corpuscles may become very much reduced in number, and structural alterations occur which simulate the appearance of parasites. The condition has been called by Hayem, pseudo-parasitic. The white corpuscles in some cases are augmented in number, in other cases they remain about normal, and Hayem thinks it probable that these are cases of epitheliomata. The hæmatoblasts may increase in number owing to their not having sufficient nourishment to turn them into red cells. In the great majority of cancers of the stomach, according to Hoeberlin, the hæmoglobin diminishes to the extent of about fifty per cent.

It will be seen from the foregoing that aside from the rational signs of cancer of the stomach, we have a number of factors which may throw much light upon the real nature of the disease; and the physician will be hardly justified in hesitating in his diagnosis until he has obtained as much light as possible from the records furnished by careful examination of the gastric juice, the urine, and the blood.

THE COMPULSORY ENGAGEMENT OF WOMEN PHYSICIANS IN STATE ASYLUMS AND HOSPITALS.

A BILL to provide women physicians in State asylums and hospitals where women patients are restrained, has passed the State Senate at Albany, and it seems to be in a fair way to become a law.

This we understand to be the bill of which the purpose is to compel superintendents of lunatic asylums to employ female physicians for the female wards. No law of such a character ought to be enacted. It is founded on a mistaken sentimentalism, and is a kind of special legislation likely to interfere with hospital discipline and work serious harm.

The number of good women physicians is limited, and those who are desirable will not for the most part care to take poorly paid work among female lunatics. It would only be among recent graduates without practical experience that candidates for the positions could be found.

More than this, it is a very well-known fact that, as a rule, women do not want to be attended by women doctors, and it is hardly fair to take advantage of their lunacy to impose such upon them by law.

We believe that there should be women physicians as assistants in our lunatic asylums, when the medical superintendent finds it desirable. The women should be allowed to compete for and hold the positions if they have the merit. But, as we have already said, it is merit and experience, not sex, or age, or color, or condition by which medical attendants should be selected.

OUR FRIENDS ARE UNREASONABLE.

Every little while we find it necessary to say a few words by way of remonstrance, if not of gentle reproof, to some of our kind and highly esteemed, but somewhat impetuous and unreasonable, correspondents. Not long since we were quite severely taken to task for having printed a signature incorrectly, and our offended correspondent spoke in a questioning manner of our lexial powers, in fact he asked bluntly if we could not read yet. Our friend had learned wisdom by experience, and wrote his second communication on a letter head with his name printed at the top. So now we know who he is, a thing that we could never have guessed from his signature. It seems to be the sole aim and object with many people to write a signature that can never by the slightest chance be read by anyone who is not familiar with it, and yet they seem actually hurt if one confesses his inability to decipher it. There is, of course, no law against this, and no one would ever object to it, if the writer would only, when writing to strangers, use paper with his name clearly printed on it. Then he could write his signature in Arabic if he preferred and no one would care a picayune. But if he omits this simple precaution, he is himself responsible for any mistakes that his correspondents may make, and we certainly will not shoulder the blame.

A word on another subject. Contributors will please not send their manuscripts rolled up; let them be sent either flat or folded, but never rolled. Some of our exchanges even come in that shape. They ought to be ashamed of themselves.

BROWN-SÉQUARD'S REJUVENATOR ONCE MORE.

The newspapers have for a long time been silent on the subject of the rejuvenation of old men by means of the injection of testicular juice, and many people have doubtless nearly forgotten that such a thing was ever talked about; but the venerable discoverer of this odd form of stimulant has by no means forgotten it, and his faith in its efficacy grows stronger every day. He has recently published a brochure recounting the details of the method and producing additional evidence of its value.

He does not think much of the greater number of the experiments made in this country and reported with such minuteness of detail in the newspapers. Numbers of physicians or rather quacks (*plusieurs médecins ou plutôt des médicastres et des charlatans*), he says, knowing nothing whatever of the proper method of procedure, gave injections of testicular juice to old men or those worn out by disease or sexual excesses, doing them no good and exposing them to the greatest risks if nothing worse. He of course rejects all such experiments as worthless, and accepts only those which have been carried out in a scientific manner by scientific men. The best of these, he says, reports of which he has seen, were those of Variot, of Paris, Villeneuve, of Marseilles, and Loomis, of New York. Even these were not wholly satisfactory, for in many cases the experiments were made on invalids and not on those who had no malady but old age, and in none of the instances were the experiments extended through a sufficient length of time to test their real worth. In his own case the good effects of the injections were observed for about four weeks after the last one was made, but then a rapid decrease in strength was noticed, and in a comparatively short time his condition was just the same as before he began. This was, he believed, an additional proof of the efficacy of these injections. He does not say whether he has again resorted to the remedy, but we suppose that he has, for with such a blessing within his reach we cannot imagine that he would refuse to stretch forth his hand and grasp it.

But there are other virtues which the testicular juices possess which we would never have imagined to reside in them had not they been discovered by experiment. Dr. Suzor, of the Island of Mauritius, has practised injections in certain cases of leprosy with the most gratifying results, the ulcers rapidly cicatrizing and the patients regaining appetite and strength. The same experimenter reports a case of malarial fever, occurring in a woman, in which one injection sufficed to arrest the daily paroxysms immediately and to remove permanently the feeling of languor and the jaundice from which the patient was suffering.

As a result of his study of these various experiments and of his personal experience, Dr. Brown-Séquard is more firmly persuaded than ever of the value of his discovery. "There is no doubt," he says, "that injections of the dilute juice extracted from the testicles of living or recently killed animals exert a marked dynamogenic action upon the nervous centres, at least in a large number of cases. There is also no doubt that these injections are without danger when they are made with those precautions which intelligent physicians know to be necessary when animal matter is to be introduced beneath the skin."

We can but express the hope that the mental and physical powers of this venerable savant may be preserved for many years in all the vigor of early manhood by means of injections of this wonderful dynamogenerator.

VACCINATING AGAINST THE DISTEMPER.

A very interesting contribution, both to lovers of dogs and to lovers of science, is made by Mr. Everett Millais in the *British Medical Journal* of April 12th. He has been making bacteriological studies of distemper in dogs, and he thinks he has found the cause and the means of preventing this malady, so fatal to canines.

The pathogenic microbe he states to be a bacillus, which he calls "bacillus B." This liquefies gelatine, descending as a flaky mass in the almost clear fluid, which is covered by a whitish scum. Finally, when the whole of the gelatine is liquefied, the flakes gather at the base, and, if stirred, appear to be of a ropy consistency.

Inoculations of pure cultures of this micro-organism caused typical distemper in dogs. When pneumonic complications were present there were always micrococci as well as the bacillus B. found in the tissues.

Growths of the specific bacillus were heated to 60° C. for 60 minutes and then diluted with sterilized water. Injections of this fluid were then made beneath the skin of eleven dogs. These animals were subsequently inoculated with the secretions of distemper and kept in infected kennels. Four had no distemper, five had it in a mild form, two in a severe form, and one died. Mr. Millais adds that he was allowed to make protective inoculations on two puppies out of seventeen owned by a

St. Bernard breeder. Distemper broke out in his kennels and all but the two inoculated puppies died. Mr. Millais thinks that he will be able to prepare an efficient protective virus against distemper.

THE STORY OF SOME COMMON MEDICAL WORDS.

THE *British Medical Journal* has been extracting interesting items from a dictionary. The work in question is the new English Dictionary, on Historical Principles, by Murray, and it contains many curious accounts of medical as well as ordinary terms. The editor only goes from "cast" to "clivy," but he finds something new about "catarrh," a word originally applied only to a running from the nose, and "cirrhosis," a word from *kirros*, yellow, and applied originally by Laënnec to yellowish granules in the liver.

The term chiropodist has the following curious origin: "In 1785 a certain D. Low published a work entitled 'Chiropodologia: a Scientific Inquiry into the Causes of Corns, Warts, Bunions, etc.,' and on page 83 he makes use of the expression, 'a skilful chiropodist.'" "Whether," says Dr. Murray, "the inventor put together χείρ, hand, and πούς, ποδ–, foot, to indicate that hands and feet were the objects of his attention, or whether he had in view the ready-made Greek χειροπόδ-ης, 'having chapped feet,' does not appear. The latter would justify his formation, the former better suit his meaning." Of this man Low and his new-fangled designation, the contemporary European magazine wrote: 'Classic lore . . . . has now reached Davies Street . . . . the residence of our Lucretian *chiropodist* (*Anglicè*, corn-cutter).' So that it is to the unscholarly coinage of an eighteenth century charlatan that we are indebted for a word which the editors of the New Sydenham Society's 'Lexicon' have admitted into their list under the high-sounding style and title of 'chiropodology.'"

The evolution of the name for castor-oil, and the history of chloroform, are all given in what is evidently destined to be, when finished, a very remarkable lexicographical work.

News of the Week.

Arrested for Practising Illegally.—A young physician, recently graduated from the Missouri Medical College, has been arrested in St. Louis for practising medicine without having registered. The child whom he had been treating unfortunately died, and this led to his detection.

Presentation of Portraits.—On April 22d a number of the members of the Philadelphia College of Physicians, together with several invited guests, took part in a dinner to mark the occasion of the presentation to the college of portraits of Drs. D. Hayes Agnew and S. Weir Mitchell.

Omaha Wants the Next Meeting.—The Omaha Medical Society has appointed a committee to invite the American Medical Association to hold its meeting for 1891 in that city. The committee is working actively to gain its point and has sent letters to the various medical societies in this section of the country, urging their delegates at the next meeting of the association in Nashville to vote for Omaha as the meeting place for 1891. The chief objection to Omaha is its alleged lack of hotel accommodations, but members of the committee claim that the two cities of Omaha and Council Bluffs can together provide for 1,600 guests over and above the average number without any undue crowding.

Dr. Mary A. Dixon Jones.—The indictment for manslaughter in the second degree against Dr. Mary A. D. Jones, of Brooklyn, has been dismissed, District-Attorney Ridgway having notified the court that there was no evidence upon which to try the accused. Dr. Jones has made a brave fight against accusations that would have crushed a weaker spirit, and she is to be congratulated upon the complete vindication which she has now obtained.

The Hospital Saturday and Sunday Association held its last meeting for the year in St. Luke's Hospital, on the evening of April 21st. The eleventh annual report of the organization was presented and approved. It shows last year to have been the best in the association's history, and puts the grand total of collections at $57,090.66, a gain of over $5,000 on the previous year. The association offers two prizes of $100 and $50 for two hymns to be sung on Hospital Saturday and Sunday at the synagogues and churches.

Ambulance Drill of the Twelfth Regiment.—An exhibition was recently given of the workings of the Ambulance Corps of the Twelfth Regiment, N. G. S. N. Y., in the practical duties of company bearers and in rendering first aid to the injured in camp, on the march, and in the field, when troops are engaged in active conflict. Sixteen men of the corps gave an exhibition of bandaging with Esmarch's triangular bandages, in cases of wounds or fractures, operating upon a like number of their comrades. The casualties included fractures of the lower jaw, of the knee-cap, and of the collar-bone. The method of the removal of the slightly wounded by means of improvised hand or arm seats and of the seriously injured on litters was illustrated.

A Town without a Doctor.—Presidio del Norte, Mex., a town of some 7,000 inhabitants, is said to be without any resident physician.

Poison in Celery.—Dr. Charles M. Cresson, of Philadelphia, states that he has more than once found the typhoid bacilli in the juice that he has squeezed out of celery grown near Philadelphia.—*Annals of Hygiene.*

Professor Brucke, of Vienna, has retired from the chair of Physiology at the University. The selection of his sucessor has been placed in the hands of a committee composed of four of his late associates.

Tracing Epidemics through the Milk Supply.—An act has been introduced into the English parliament granting authority to the sanitary authorities to demand a list of his customers from any milk-dealer, in order to trace outbreaks of typhoid fever or other disease to their origin.

The Physician of the King of Spain, Dr. Ocana, has been raised to the rank of a grandee of Spain, in recognition of his successful management of his little patient's recent illness.

The South Carolina State Dental Association will hold its annual meeting in Charleston on May 13.

Leprosy in Mississippi.—Dr. Griffin, Health Officer of Jackson County, Mississippi, reported the existence of a case of leprosy to the State Board of Health at its recent session.

Dr. Isidore Labatut, who is supposed to be the oldest physician in the South, if not in the United States, recently celebrated his ninety-seventh birthday. He was born in New Orleans and received his medical education in Paris. He entered the French Army and served as surgeon at the battle of Waterloo. After the fall of the Empire he returned to New Orleans, and has practised there ever since.

The Sioux City Hospital.—A hospital association has been incorporated in Sioux City, Ia., the object of which is to build and maintain a hospital in that city. It is said that the medical control of the hospital will be entirely in the hands of the medical board, the financial management being entrusted to lay members. The hospital will be unsectarian.

Illinois College of Pharmacy.—A site has been secured on the corner of Dearborn and Twenty-fifth Streets, in Chicago, for the erection of new buildings for the accommodation of the Illinois College of Pharmacy and the Chicago Medical College.

Poisoning by Canned Beef.—An investigation into a number of cases of sickness on Staten Island has shown that they were due to poisoning by canned corned beef.

The Metric System of Weights and Measures.—At the last meeting of the American Association for the Advancement of Science, held at Toronto, Canada, September, 1889, Professor Wm. H. Seaman, Washington, D. C., Dr. Fred. Hoffmann, New York, and Professor Robt. B. Warder, Washington, D. C., were appointed a committee to promote the use of the metric system of weights and measures among professional men, and especially to secure its more general adoption by the physicians and pharmacists and the chemical and pharmaceutical manufacturers of our country. This committee has recently issued an address to the physicians and pharmacists of this country and Canada, urging upon them the adoption of this system. The metric weights and measures were legalized in this country by Congress in 1866, and are now in actual use by most students of natural history, by some scientific periodicals, by the graduates of our schools of civil and mining engineering, and especially by all scientists and chemists throughout the world, without regard to their mother tongue. They are also in exclusive use by the republics of Central and South America, so that the English speaking people are almost the only ones in the civilized world who have not adopted this system. "It is unnecessary," the committee says, "to expatiate on the advantages of the metric system of weights and measures. The identity of the single factor with our system of numeration, the perfect correspondence between measures of weight and capacity, its approval by a large majority of the nations of the world, and especially its actual use by scientists and chemists without exception, render its ultimate adoption by all arts dependent on natural sciences, and especially by medicine and pharmacy, a matter of necessity and certainty." The committee further recommends that schools of medicine cease to give instruction in the apothecary system of weights and measures, for which there is no longer any reason, and that in the schools of pharmacy the merits of the metric system should be presented with the prominence that its utility, and the near prospect of its adoption justify, in the best way to secure its immediate use as the exclusive system of weighing and measuring in medicine and pharmacy, and in the manufacturing arts correlative with them.

Dr. R. F. Weir has returned to this city after a brief trip to Europe.

Operations for the Relief of Hypertrophy of Prostate Gland.—Dr. William T. Belfield, 612 Opera House Building, Chicago, Ill., respectfully solicits information concerning unpublished cases of operations upon the prostate, especially for the relief of the so-called hypertrophy of the organ.

A Medical Candidate for Mayor.—Dr. Leavitt, of Butte City, Montana, is the Republican candidate for mayor of the city. His opponents admit that he is a good physician, but claim that that very fact unfits him for the position for which he is a candidate.

Leprosy in New Caledonia.—According to the Paris *Dix Neuvième Siècle* leprosy is increasing at an alarming rate in New Caledonia. Of the forty thousand natives it asserts that fully five thousand are suffering from the disease. A few Europeans have also been attacked. The authorities have recently established two leper colonies and will try to limit the further spread of the disease by enforcing strict isolation.

The Street Cleaning Department of this city has appointed three physicians to examine all applicants for positions on the force, to determine whether they are physically fit to do the work required.

International Medico-Legal Congress.—The President of the Medico-Legal Society has received the following letter from Secretary Blaine in regard to the proposed International Medico-Legal Congress to be held in this country in 1892:

DEPARTMENT OF STATE, WASHINGTON,
April 17, 1890.

Clark Bell, Esq., President of the Medico-Legal Society.
No. 57 Broadway, New York City.

DEAR SIR: I have received your letter of the 31st. ultimo, enclosing copies of circulars which you are sending to the various countries of the world, inviting co-operation for the Congress, which will be convened in 1892 in the United States, for the discussion of medical jurisprudence. The importance of such a gathering as you propose cannot, it would seem, be overestimated. The intelligent discussion of scientific questions, especially those which so closely affect the human family, by a body of gentlemen learned in medico-legal science, must prove of especial value, and should be worthy of every effort, which has for its mission the amelioration of the condition of mankind. My individual sympathy in the objects and purposes of your conference is very great, and I trust that the results of such a meeting as you propose may correspond to the aims you have in view, as I have no doubt they will. I am, dear sir, very truly yours,

JAMES G. BLAINE.

Medical Department of Niagara University.—The Commencement of this school took place on April 15th, at which time fifteen young men were graduated. This school is one of those which have adopted a three years' graded course.

Diphtheria in an Insane Asylum.—There have been several cases of diphtheria among the inmates of the State Insane Hospital at Augusta, Me., and it is proposed to erect a wooden pavilion to facilitate the isolation of the sick.

A New Medical College.—A building is about to be erected in Chattanooga, Tenn., for the use of the medical department of the University. The new college has just completed its first term.

The Utica Medical Library Association recently adopted a resolution endorsing the bill now before the Legislature providing for a single medical examining board. In addition to endorsing the bill, the meeting voted to request the senator and assemblymen from Oneida County to support it.

The New York Cancer Hospital, One Hundred and Sixth Street and Eighth Avenue, New York.—The New York Cancer Hospital is fulfilling the design of its liberal founders by a steady increase in its patronage and a corresponding expansion of its usefulness. It is now in its second year of work, and in its annual report just published gives the following gratifying exhibit: Two hundred and forty-one patients were admitted up to January 1, 1890, as against 278 recorded in the last report, 131 being free patients; 183 operations were performed, including 12 vaginal hysterectomies and 28 laparotomies. It should be noted that 69 per cent. of the deaths occurred in patients who were not operated upon, *i.e.*, who were incurable when admitted. All of these patients have had their sufferings relieved and their lives prolonged by careful treatment and nursing; in fact, no patient has been refused admittance, however hopeless her condition. The institution is a Cancer Hospital, and cases of malignant disease, however advanced, receive the preference, as was the original intention of its founders. It is entirely dependent upon the public for financial support as regards the current expenses, and its doors stand open to all sufferers from cancer, whether they are able to pay for their board or not. The corner-stone of the new male pavilion, given by the late Mr. John J. Astor in memory of his wife, the late Mrs. Charlotte Augusta Astor, and of Mrs. Cullum's memorial chapel, were laid in December, 1889, and work is being rapidly pushed on these buildings. It is hoped that the pavilion will be ready for the reception of patients early next winter. Mr. George C. Clark has been elected to fill the office of treasurer. All patients suffering from cancer, whose condition admits of cure or relief, will be admitted by the superintendent with the approval of one of the medical officers of the hospital. Patients who are too ill to present themselves in person will, on proper application, be visited and examined by one of the medical officers of the hospital. Patients living out of town should submit to the superintendent an application in writing, accompanied by a statement of their case by some responsible physician, before presenting themselves at the hospital. The charge for board in the wards and private rooms is at rates fixed by the executive committee. These rates include all expenses, except those of a special nurse. All charges may be remitted in whole or part by the executive committee, or, in the intervals of its meetings, by the superintendent. At present the charges for board are: $7 per week for patients in the wards; $20 per week for patients occupying single private rooms; and $15 per week for patients occupying double private rooms.

Cheapening Medical Services.—Eleven physicians in Cleveland, O., have offered to take charge of the City Hospital and give their services without compensation. The hospital is at present under the care of one physician, who receives a salary of $1,200, and his eleven generous confrères propose to take the burden off his shoulders and deprive him of his salary. It is said that one of the eleven has a charter for a medical college in his pocket, and if clinical facilities can be obtained, the new college will be established.

The Medical College of Guy's Hospital.—On Wednesday, March 26th, Mr. Gladstone opened the new buildings of the Medical College at Guy's Hospital, London, which afford accommodation, board, and lodgings for a certain number of resident medical students, with an increase of the working hospital staff. The college is built in quadrangular form of red brick, in what is known as a revised Elizabethan style. The front entrance, guarded by two handsome oak gates, is opposite the Maze pond gate of the hospital. The college is now finished and ready for occupation. It consists of dining-hall, reading-rooms, and gymnasium, all available for members of the students' club, and accommodations for the junior members of the staff at present lodged in the hospital, and for fifty resident students, with a suitable residence for Dr. Perry (Dean of the Medical School), who will be the First Warden of the College.

Failure of a Malpractice Suit.—Dr. W. S. Gleason, of Newburg, N. Y., was sued recently for alleged malpractice. He was called to see a man who had received some injuries while intoxicated. Examination showed that there was a dislocation of the shoulder complicated with fracture of the humerus. Dr. Gleason reduced the dislocation by a happy chance and then set the fracture. On the next visit, however, he found the dressings disarranged and the head of the humerus again dislocated. It was then impossible to reduce it. The man sued, alleging that the surgeon fractured the arm while attempting to reduce the dislocation. The jury found no cause for action and the defendant was acquitted. From the testimony presented, Dr. Gleason had evidently managed the case in a most skilful manner, and we congratulate him upon his escape from an unjust persecution.

The Ladies' Health Protection Association.—An association with this name has been formed in Brooklyn and has recently become a legally incorporated society. It intends, about the middle of May, to hold a conference to consider the best steps available and advisable for the purpose of interesting housekeepers in the proper disposal of garbage, in aiding to keep the streets clean, and in adopting measures for securing the effective execution of the Health Laws. An organization having a similar object has been in existence in this city for a number of years.

St. Luke's Hospital, Denver.—Plans have been perfected for the erection of a new building for St. Luke's Hospital in Denver, and about $135,000 has already been subscribed for the purpose.

American Students in Berlin.—The names of the American students lately dismissed from the Berlin University are Clarence Kellogg, Dr. William Porter, Dr. William A. Duranger, William Kelley, Richard Schulenberg, and David Jamieson. Dr. Hinschins, Rector of the Berlin University, was asked why that institution refused to recognize medical degrees conferred by American colleges. He refused to discuss the subject. Privy Councillor Klueffel said that American colleges differed so greatly, those of excellent standing existing side by side with bogus affairs, that the authorities of the University could not take the time and trouble to distinguish between them. Herr Schmitt, Curator of the University, said that probably the omission of American degrees from the register was due to the laxity of the American laws and regulations regarding the conferring of degrees. Meantime, the American physicians feel the position acutely, although they are fully recognized and highly esteemed by the medical society of the German capital.—*London Illustrated News.*,

Medical Saloon-keepers.—There is a lucrative opening for medical men in Iowa, not exactly as practitioners, however. The Iowa Legislature, which adjourned about the middle of April, passed what is called the Pharmacy bill, conferring upon physicians the right to dispense liquor, and placing upon them no restraint whatever. They do not need a permit, like the druggists, nor is there any supervision of their manner of prescribing in the sales they make. There are about 5,000 doctors in the State, and if this law is to remain in force the number of "docs" will soon be beyond computation.

Great Ormond Street Hospital for Sick Children.—On March 26th the corner-stone of the new, or "jubilee" wing, which will complete this hospital, was laid. The wing is called "jubilee" because the Queen contributed about one-fifth of the expense of its construction out of the children's jubilee tribute in 1887.

A Medical License to Marry.—Dr. J. M. Emmert, President of the Iowa State Medical Society, delivered an address at the annual meeting of the society, on April 16th, in which he advocated compulsory medical examination of those intending to wed, and held that no licenses to marry should be granted except on a reliable physician's certificate that the parties desiring to wed are physically sound and qualified for the matrimonial relations. He also maintained that the discovery that either party is constitutionally diseased ought to be sufficient ground for securing a divorce.

A Hospital Condemned as Unsafe.—The Louisville (Ky.) City Hospital has been examined by a committee of architects and pronounced to be wholly unsafe, unhealthy, and in unfit condition for the reception of patients or for anybody else. The committee found that the wood flooring was rotten, and in several of the stories had settled at least two inches. They also said that the elevators and everything connected therewith were in bad condition, and they advised that the building be torn down before it fell down.

Leprosy in San Francisco.—The Board of Health in San Francisco is busy discussing the problem of how to combat leprosy. The disease is said to be constantly making greater inroads upon the white population, and the advisability of establishing a lazaretto is seriously considered. At a recent meeting the Board appointed a committee to examine into the matter, to ascertain the cause of the rapid increase of leprosy, its contagiousness, the extent of its inroads upon the white population, and the best methods for its removal.

The New Haven Hospital.—Plans have been completed for the erection of a new wing for the New Haven Hospital. This extension was made possible by the recent acquisition of $50,000 from the Gifford estate. Owing to the crowded condition of the wards it was decided to build a ward for incurables. The extension will be 150 by 26 feet and three and a half stories, the same as the main building. It is intended to build so as not to exceed the $50,000 at command. As soon as the plans are approved a move will be made toward advertising for bids, and it is expected that the building will be well advanced by the end of the summer.

The Late Dr. John W. Jackson, of Kansas City, whose death we recorded a short time ago, was the first Vice-President of the American Medical Association.

Obituary.

FREDERICK A. KINCH, M.D.,

WESTFIELD, N. J.

Dr. Kinch died in Westfield, N. J., Sunday, April 27th, aged sixty-eight. He had been forty years a practitioner in that neighborhood, where he commenced and ended his professional career. Dr. Kinch lived beyond the average age of physicians, which is nearer sixty than seventy years. His life was a successful one, in many ways. He was the architect of his own fortunes, and whatever he accomplished, to him alone the credit was due.

He was a diligent, hard worker for all these forty years, in a hard profession, and in a practice extending over a wide territory. He accumulated a fortune, and on moderate fees. He was active in public affairs, doing much all his life in the interests of the public; a man highly esteemed and trusted by the community in which he lived. His death is a great loss to the profession, to his patients, and to society. He leaves a widow and two sons, their only children, Charles A. Kinch, M.D., of New York City, and Frederick A. Kinch, M.D., of Westfield, both engaged in the practice of medicine.

To live an unspotted life for sixty-eight years, to practise medicine for forty years of that time, and accumulate by industry and frugality a fortune for his surviving family, leaving two sons educated practising physicians, is much to show at the close of the life of an M.D.

C. B. R.

HENRY V. HULL, M.D.,

SCHENECTADY, N. Y.

Dr. Henry V. Hull died of tuberculosis at his home in Coeymans, N. Y., April 27th, aged thirty-eight. After graduating from the Albany Business College, he obtained his medical degree from the Medical Department of Union College in 1874, and became Medical Interne of the City Hospital at Albany. He then removed to Schenectady, where he continued to practise until stricken with disease. He maintained a high rank among his confrères, who mourn his untimely end.

Society Reports.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, April 21, 1890.

GEORGE T. HARRISON, M.D., PRESIDENT.

Recent Criticisms on Credé's Method of Placental Expression.—DR. W. T. LUSK read the paper. Before the introduction of the Credé method the profession was divided, with reference to placental expression, into two classes, namely, those who believed, except in cases of hemorrhage, that the placenta should be left to nature, and those who made traction on the cord. We now know, however, that the introduction of the hand, and traction on the cord are attended by certain dangers, including infection, while mere passivity renders hemorrhage more probable. The Credé method consists in first applying light and afterward stronger friction to the fundus of the uterus, until an energetic contraction is obtained. At its height the uterus is grasped so that the fundus rests in the palm of the hand, and the body is pressed between the thumb and fingers. The effect of external pressure thus exerted is to force the placenta from the uterus, or, in case of failure, the process is to be repeated. In experienced hands it is likely to be expelled by the third or fourth uterine contraction.

As compared with old methods, the reader said, it consisted essentially in the substitution of external manipulation for the internal use of the hand. He had found no obstetrical manœuvre which he delighted as much in when teaching the young practitioner. But within the last few weeks a statement had been going the rounds of the medical journals, to the effect that Credé himself had abandoned the method. It was, however, anonymous, and seemed to be entirely without foundation. It was true that during the last ten years many protests had been made against early disturbance of what had been regarded as the normal forces, by means of which expulsion of the placenta was effected. After briefly reviewing some of the recent criticisms of Credé's method, the author said that, in his opinion, the only question at issue was whether the method was physiologically justifiable, and what interpretation was to be placed upon Credé's advice to express the placenta as soon as possible after the birth of the child. Statistics showed that the method did not increase the quantity of blood lost, and that unless resorted to too early it did not produce tearing and retention of the membranes, and if this latter accident should occur, it would not, with rigid antiseptic conduct of the labor, enhance the risks of puerperal fever. It seemed tolerably clear that, in most cases, the first fifteen or twenty minutes after the birth of the child the placenta left the uterine cavity either in whole or in part, and then offered all the conditions favorable for expulsion. But if left to the unaided efforts of nature, long delay usually took place after the placenta had sunk into the lower uterine segment, so that it was a good rule, accepted of late by Credé likewise, not to resort to external manipulations until at least fifteen minutes had expired; some advocated a delay of thirty minutes.

According to Dr. Lusk's experience, when, as a result of expulsion, the placenta appeared at the vulva, the uterus often contracted and became hard while a considerable portion of the membranes were yet in its cavity, and hasty traction would be likely to tear off a portion of the placenta.

DR. A. P. DUDLEY would simply steady the fundus of the uterus for fifteen minutes after the birth of the child, and then resort to Credé's method.

DR. JOSEPH KUCHER had never found any of the drawbacks to Credé's method which had been mentioned by its critics.

DR. H. J. BOLDT also strongly approved of the method, and regretted that some men did not appreciate it, because not using it carefully and properly. As to the retro-placental clot, he did not believe it took place before the birth of the child, but he had observed it both where Credé's method was practised and where the case was left entirely to nature.

DR. MCLOUD thought the Credé was the ideal management of the third stage of labor, DR. OBERNDORFER practised it, while DR. BROWN expressed himself as more disposed to trust in nature, and DR. AXETEL inquired how long expression should be tried before introducing the hand to clear the uterus of the membranes.

THE PRESIDENT thought the position assumed by Dr. Lusk was unassailable. As to the method of expulsion of the placenta, he believed in some cases it descended edgewise, and that in others blood-clot formed behind it according to the mechanism explained by Schultze.

DR. LUSK said, in closing the discussion, that, while some of the leading men in Germany almost prohibited the Credé method, yet he thought the accidents attributed to it, such as post-partum hemorrhage, retention of the membranes, and puerperal fever, had no foundation. As to how long the Credé method should be practised, he said that personally he could succeed in expressing the placenta during the course of three or four uterine contractions in ninety-nine cases out of a hundred. Where there was adherent placenta, and expression could not be effected in three or four pains, he would not hesitate to pass up his hand and remove it.

Pink Eye.—DR. J. HERBERT CLAIBORNE read a paper on this subject. He first described the clinical features of the disease at the height of the attack. The lids are swollen and red, varying directly with the severity of the inflammatory process; the veins of the upper lid are often visible; the edges of the lids are covered with yellowish, sticky secretion; the lashes bound together; often a bead of yellowish dry matter lies in the inner corner of the eye; the lids may be glued tightly together in the morning. Depressing the lower lid and turning back the upper, one will find the mucous membrane red, swollen, succulent, bathed in secretion. In the bottom of the sac are strings of yellowish-white matter; in many cases there are granulations of the lower lid. The eye is pink in all cases in which it is not red, but the author thought the name red eye more appropriate than pink eye. The blood-vessels of the subconjunctival region and the superficial ones are congested. The cornea is rarely affected. When affected it is only phlyctenular, the deeper structures of the ball not being involved. On the whole, the general characters of the disease are catarrhal. Usually only one eye is first affected, later the other also. Severe cases are always attended with coryza, and frequently by inflammation in the frontal sinus. Systemic depression, with fever and sleeplessness, are not infrequently present. There is but slight photophobia. As the severe stage passes, the eye shows less catarrhal influence; the pink fades away; the majority of cases recover in from four to six weeks. The prognosis for sight is good.

All observers were agreed in considering pink eye a distinctly catarrhal process. Dr. Claiborne stated that all cases were contagious, most of them infectious, and as to name, he thought the most appropriate was acute catarrhal infectious conjunctivitis. The diagnosis was not difficult, and as to treatment, most cases would recover of themselves within four to six weeks if the patients were attentive to personal cleanliness and hygiene. Yet rational mild treatment would facilitate recovery, while harsh treatment would retard it. As far as possible members of a family having the disease should be separated from others; children should be kept from school. As a rule, a month was sufficient time for quarantine. As to topical treatment, he believed cold applications to be best, at least in the acute stage; ice-cold pledgets from borax water—a teaspoonful to half a pint or a pint of water—applied to the lids several times a day. If granulations were present some astringent might be called for. Regarding the etiology, it had remained for Dr. Weeks to claim that pink eye was due to the pres-

ence of a small bacillus in the conjunctival sac which differed from all other bacilli yet found; but a pure culture had not been made, and the author expressed doubts regarding this origin of the affection. He referred to an epidemic which had started from two boys who appeared to have got the disease while bathing in the North River.

His conclusions were as follows: Pink eye is an acute catarrhal disease of the conjunctiva. It is usually infectious; always contagious; sometimes sporadic. The cause is undetermined, but is evidently an entity transmissible through the air and communicated by contact. The prognosis is good. The duration of the disease is four to six weeks. The treatment is by cold, antiseptics, mild astringents, salves.

Dr. N. J. Hepburn did not recollect to have seen as severe a case of pink eye as had been described in the paper. The cases which he had seen were without discharge, or with very little; nor did he recall a case in which there was swelling of the lids or granulations. Most of the cases got well without special treatment. At one period there would be a considerable number; and at others none.

Dr. John E. Weeks discussed points raised in the paper at some length. The granulations of the lower lids spoken of were not the true granulations of trachoma, but were simple inflammatory hypertrophy of the papillæ. They disappeared in a short time as the disease subsided. He thought those acquainted with the experiments made with the small bacillus discovered by him, and referred to in the paper, must become convinced that it was the cause of pink eye. He had lately succeeded in making a pure cultivation of it, of which he exhibited photographs. The author had criticised the suggestion to use secretions of pink eye for inoculations in trachoma. Dr. Weeks said he had not made the suggestion with the idea of acting on it himself, but for the benefit of those who were using inoculations of more destructive agents.

TENNESSEE STATE MEDICAL SOCIETY.

Fifty-seventh Annual Meeting, Held in Memphis, Tenn., April 8 and 9, 1890.

The Society was called to order by the President, Dr. Duncan Eve, of Nashville, at 10 A.M.

The Address of Welcome was delivered by Dr. D. D. Saunders, of Memphis.

Incontinence of Urine in Children was the title of a paper read by Dr. A. J. Swaney, of Gallatin.

The various causes of this affection he tabulated as follows: 1. Excessive acidity of the urine, which is usually caused by excessive formation of uric acid. 2. Over-irritability of the muscular coat of the bladder, even when the urine is neutral. 3. Weakness of the sphincter. In such a case the urine is not passed as rapidly, or in a full stream, as when the cause is in a forcibly acting detrusor. 4. From reflex action. Any source of irritation in or about the genital tract may be a cause of incontinence of urine. Local examination may discover a balanitis or adhesions between the prepuce and glans penis, with smegma around the corona. Two such cases had come under his observation in the last year. 5. Too great a quantity of urine, from the child drinking too large a quantity of fluids. 6. Vesical calculi. 7. Malformation of the bladder. Several cases have been reported where persistent and irremediable incontinence was induced by one or both ureters opening into the urethra. 8. Contraction of the walls of the bladder, owing to hypertrophy of the muscular layer reducing the capacity of the bladder to one or two ounces. This he found to be the condition of the bladder in a case which he would report. The walls of the bladder were contracted so much that the patient's bladder would not hold more than one and a half ounce of water.

Treatment of Incontinence of Urine.— This must depend upon the discovery of the proper cause in each specific case. Where the urine is highly acid it should be neutralized by the administration of alkalies. The acetate of potash is one of the best preparations for this purpose. Fruits often do well in children old enough to partake of them, as the vegetable acids are changed to alkaline bases in the system. Where the fault is from the detrusor acting too vigorously, belladonna serves as a specific. Five drops of the tincture of belladonna may be given three times a day at first and the dose increased by single drops, until there is some dryness of the throat and flushing of the skin. If the drug is to control the incontinence at all, it will do so when such effects are produced. For a lack of force in the sphincter ergot in full doses is indicated. A good effect follows the injection of five or six drops of the fluid extract of ergot into the connective tissue of the ischio-rectal fossa, as recommended by Dr. H. D. Chapin, of New York. In all cases of incontinence of urine everything possible should be done to tone up the nervous system, and to this end the speaker mentioned syrup of the iodide of iron and strychnine in full doses as being very valuable.

Dr. T. J. Happel, of Trenton, contributed a paper entitled "A Résumé of Surgical Cases in a Country Physician's Practice," in which he outlined his general method of procedure at considerable length, and then said that the nearest approach to what might be termed "ideal surgery" that it had been his lot to deal with, was one of his latest operations—the removal of what appeared to be a cancerous degeneration of a nævus or mole in an old lady, nearly ninety-three years of age. This tumor had attained to the size of a duck egg, was growing on the left temple, and had developed rapidly within less than six months. It was removed under chloroform on April 21, 1889, and the patient was dismissed cured on May 5th. There was no elevation of temperature, and less than one-fourth of a teaspoonful of pus was found.

In all his operations he used chloroform.

The speaker believed in antiseptic surgery, inasmuch as it forced upon us greater cleanliness, but he was not yet fully satisfied that the micro-organisms which are supposed to be destroyed by antiseptic lotions, etc., are the causes of the disease. They may be simply sequences. The disease may furnish them suitable pabulum upon which to grow, and they develop as a result of the disease. Perhaps, after all, the antiseptics only prevent the furnishing of this *tertium quid* on which the bacilli and micrococci grow and thrive.

Dr. G. W. Drake, of Chattanooga, read a paper on "The Triune Man," Dr. N. T. Dulaney, of Bristol, one entitled "Hypermetropia," and Dr. P. H. McKinnie, one on "Pneumonitis and its Treatment."

Endocarditis and its Differential Diagnosis, was the title of a paper read by Dr. J. A. Witherspoon, of Columbia, in which he said that the correct diagnosis of heart affections depends upon a thorough understanding of the anatomy and physiology of the organ. He then offered a plea for more thorough examinations, to satisfy ourselves what lesion of the heart exists. We should not be content with the unscientific diagnosis of "heart disease." It is the sacred duty of the physician to investigate thoroughly and closely before pronouncing the benediction on the activities of a man's life, by saying that he has organic heart disease. Endocarditis occurs in three varieties, viz., exudative, ulcerative, and interstitial. The speaker confined his remarks chiefly to exudative endocarditis, which occurs usually in those diseases in which there is marked dyscrasia of the blood, where that fluid is altered in its histological proportions or physiological elements, and especially in acute articular rheumatism, for it occurs in about thirty-three per cent. of such cases. It may occur in any disease in which there is a morbid state of the blood, such as the exanthemata, essential fevers, diphtheria, nephritis, pyæmia, etc. It may occur, as a primary disease, from exposure to cold, violent efforts, blows or other injuries to the chest, and it sometimes occurs without any discoverable cause. Its

most frequent site is upon and around the valves, hence the liability to the production of valvular troubles, and it is generally found upon the left side of the heart.

Diagnosis.—Endocarditis is usually associated with signs of acute pericarditis, swollen and painful articulations, and the acid sweats of rheumatism. The differential diagnosis between endocarditis and pericarditis would not be difficult, were they not so often associated together. In pericarditis we have no murmur, but a to-and-fro friction sound; the impulse of the heart is more feeble and distant, and in the later stage, marked enlargement of percussion dulness; the sounds of the heart are very feeble and muffled in pericarditis, whereas they are even more distinct—except at the site of the murmur—and normal, in endocarditis. The only other disease for which endocarditis may be mistaken, is aortitis, especially if the inflammation is in the first part of the aorta. The diagnosis between them is said to be very often impossible to make, the only distinguishing features being the increase of pain, which extends along the trunk of the vessel, with marked pulsation and a blowing murmur, which is transmitted in the direction of the blood-current, and a diffused sensitiveness of the arterial system.

Complications.—There are two complications of endocarditis which cause entire change of symptoms. One is, that the fibrin which deposits upon the inflamed endocardium may be so large as to form a clot, and if this clot is large enough, then symptoms of obstructed circulation to a most alarming extent manifest themselves by a condition of collapse; the skin becomes cold and cyanotic, the pulse thready and weak, and the heart's action exceedingly irregular, with great struggling for breath. The murmur becomes indistinct, and cardiac dulness is slightly increased; fainting spells alternate with nausea, vomiting, often delirium, and death comes on in a very short time and closes the scene of most terrible suffering. Then, too, we may have a small clot of fibrin or vegetation from the valves washed into the circulation and carried to different parts, when the well-known signs of emboli will appear.

Ulcerative endocarditis is usually septic in its origin and is of rare occurrence. This fatal type of the disease is manifested by great prostration, with marked typhoid symptoms, irregular chills, profuse sweats, extremely rapid pulse, dry red tongue, muttering delirium, followed by vomiting, diarrhœa, deep jaundice, and stupor; marked tenderness is found over the liver and spleen by palpation; great dyspnœa with Cheyne-Stokes respiration, and a scanty, highly colored albuminous urine.

Dr. Duncan Eve, of Nashville, delivered the presidential address. He selected for his subject "Recent Progress in our Profession." He said the valor, the prudence, the wisdom, the patient industry, the zeal, the accurate observation, the critical examination, the continuous contemplation, the superior learning, and the great ability engaged in the advancement and development of this department of our science and art, have been crowned with the happiest results. What heretofore would have startled, now becomes commonplace. What once defied the utmost powers of the imagination to conceive, now becomes the real occurrence of every-day life.

Surgery has taken old and familiar agencies, and found in them either a new value, or discovering their worthlessness, has used and applied others in their stead. It has invented new instruments and appliances, and found new and better uses for those heretofore known. It is continually enlarging its province, and ascertaining and defining its boundaries.

Dr. Bayard Holmes, of Chicago, read a paper on "Secondary Mixed Infection in Scarlet Fever." He said that no one doubts to-day that scarlet fever is due to an obligate parasite, and the fact that this parasite has not been cultivated on artificial media and studied is due to the fact that it has become so perfectly adapted to the human host that it can exist in no other, and on no artificial media. It must be studied in the same manner as the *plasmodium malariæ*. Everything points to the fact that scarlet fever is a septicæmia self-limited in its nature, finding its atrium of invasion in the pharynx and probably in the tonsil, and manifested by all those symptoms which characterize septicæmias of other kinds. One of the most frequent symptoms of an unfavorable course of scarlet fever is the enlargement of the cervical lymph-glands. These glands are found crowded with chain cocci, and the same condition may be traced to the tonsils and the walls of the pharynx, the connective tissue of which is found crowded with the same streptococci.

Phenic Compounds in Germ Diseases.—Dr. W. F. Glenn, of Nashville, read a paper with the above title. He said, by the experiments of Pasteur and Tyndall and others, the fact that many, if not all diseases, are due to the presence and active development of living germs in the system, has been thoroughly established. The development of germs in the living system is as properly called fermentation, as is a similar process in the wine-vat in the formation of wine. If any agency be employed which directly lessens the fermentive process, just in the same proportion is the temperature lowered, and *vice versa*. So we find in the human being, in all zymotic diseases, when the fermential microbe is introduced into the blood, there finding its natural element, its development or multiplication begins and an immediate elevation of temperature takes place. Just in proportion to the activity of this multiplication of disease cells, their rapidity of development, so is the fever higher and the symptoms graver.

If we can introduce into the blood or apply to a given part any substance that will destroy the life of these disease germs, we will have reached a perfection of scientific treatment.

From the experiments of Dr. Calvert, it is known that the salts of quinine, in solution, will destroy all vegetable fermentation, the salts of mercury in solution all animal fermentation, and a solution of pure carbolic (phenic) acid both. Can we put a sufficient amount of carbolic acid in the blood to arrest and prevent the growth of disease germs with safety to our patient? Yes. The accidents heretofore attributed to the administration of carbolic acid have been due to its impurity more than to the quantity given. If absolutely pure, it is a safe and efficient remedy; if in the least degree impure, it is a very dangerous one.

Dr. Glenn has used Dr. Declat's preparations of phenic acid, both internally and externally, with gratifying results, for the last ten years. During this time he has employed phenic acid as his chief remedy in all cases of malarial, typhoid, and scarlet fevers, diphtheria, erysipelas, blood poisoning, as a local application to all wounds, whether the result of accident or surgical operation, and has found the result so satisfactory that there is little left to be desired.

Since he has been following this plan of treatment, in typhoid fever, for example, he has never had a diarrhœa occur in any of his patients; never a hemorrhage from the bowel; never a serious tympanites; never a death. He believed that with phenic acid, and antifebrin as an aid, physicians possessed the treatment, *par excellence*, of all zymotic diseases.

Dr. B. P. Key, of Chattanooga, read a paper entitled "Report of Seven Cases of Ovariotomy in the Last Year."

In these seven cases he had had but one death. The history of this case was as follows:

Mrs. H——, aged thirty-five; married about ten years; mother of three children. During the last three years she had suffered intensely from dysmenorrhœa; general health impaired, and the best part of the time was spent in bed; she had constant pains in the right and left ovarian regions. He stated to the patient's family that there was no chance to save her life, except by doing a laparotomy. She readily consented to undergo the operation. For the first twenty-four hours after the operation, she appeared to rally and continued to improve until the fourth day had passed, when the heart commenced beating very

rapidly, and she at once became very restless. The ovaries were enlarged and contained pus. Patient died on the fifth day.

Dr. F. T. Smith, of Chattanooga, read a paper on "Blindness," which was followed by a contribution on "Eye Symptoms in General Medicine," by Dr. J. L. Minor, of Memphis.

Dr. J. S. Cain, of Nashville, read a paper on "The Use and Abuse of Antipyretics."

The condition of pyrexia is the result of two distinct processes, one the increase in heat production, the other a decrease in heat dispersion, acting either singly or together. When in health or in a physiological state, these two processes exist in such harmony and perfect equipoise, that no matter what may be the circumstances surrounding the individual, the body temperature remains practically at the same standard of 98.5° F., which we term normal temperature.

Certain disease producing agencies, gaining admission into the economy through the lungs, stomach, or other avenues of invasion and acting through the nervous system, interfere or destroy this equalizing process, and result in the accumulation of an undue amount of heat in the tissues and blood, and constitute the condition usually termed fever, to which is attached so much importance as a factor in disease.

That there is danger from long-continued hyperpyretic temperature he had no doubt. But the symptoms of degeneration of the various organs above mentioned seem—to use the language of Dr. von Ziemssen—"not to be the effects of high temperature, but coincident effects of the cause of the fever, and the cause is infection."

Dr. Cain was convinced that pyrexia is not only most often an unimportant factor in disease, which does not require any special treatment, but that sometim s and in certain characters of fever, it is one of nature's efforts at repair which should be encouraged, and to combat or antagonize it, in the sense of arresting its generation, is to try to defeat the very conservative and reparative processes by which nature is struggling to preserve the life of the patient.

Antipyretic Remedies.—These are very properly divided by Dr. Brunton into two main classes, those which lessen the production of heat, and those which increase its loss. The first class is subdivided into those remedies which lessen production by arresting tissue metamorphosis. At the head of this class stands quinine; also those which lessen oxidation by controlling the circulation and cutting off the oxygen supply which is furnished alone by the blood. These are usually nerve and heart sedatives, and means which retard the active flow of blood.

Antipyretics are again divided into general and local remedies. Under the head of the former class (leaving out venesection, now no longer practised) may be mentioned antimony, ipecac, aconite, veratrum viride, gelsemium, and the new and just now much used products of coal tar, antipyrine, antifebrine or acetanilid, phenacetine, and others. The therapeutic action of these latter remedies in controlling temperature is not well understood, but when we consider their direct depressing effects upon the medullary and spinal centres, and observe the marked cyanosis nearly always attending their free administration, the conclusion is almost irresistible that they retard oxidation, and by their powerful sedation lessen the supply of oxygen to the tissues, like the other agents mentioned, and lower temperature by arresting combustion.

The following papers were also read:

"The Abuse of Quinine," by W. C. Bilbro, M.D., of Murfreesboro; "Suppurative Inflammation of the Middle Ear," by J. G. Sinclair, M.D., of Nashville; "Fractured Thigh: Easy Method of Treatment without Long Splint or Pulley," by J. W. Davis, M.D., of Smyrna; "Hysterectomy for the removal of a large Subperitoneal Fibroid," by W. E. Wilson, M.D., of Pulaski; "Fracture of the Lower End of the Radius with Complications," by J. W. Brandon, M.D., of Stribling; "Foreign Body in a Child's Stomach," by S. W. Sanford, M.D., of Henning; "The Importance of Early Treatment in Middle Ear Disease," by N. C. Steele, M.D., of Chattanooga; "Euplis, with Report of Five Cases," by W. B. Rogers, M.D., of Memphis.

Officers for 1891.—*President*—Dr. G. A. Baxter, of Chattanooga; *Vice-Presidents*—Drs. S. W. Sanford, of Henning; W. G. Ewing, of Nashville; N. T. Dulaney, of Bristol; *Secretary*—Dr. D. E. Nelson, of Chattanooga; *Treasurer*—Dr. J. P. C. Walker, of Dyersburg.

Place of next meeting, Nashville, Tenn., second Tuesday in April, 1891.

Correspondence.

THE ACTING ASSISTANT SURGEON'S BILL.

To the Editor of the Medical Record.

Sir: As I have received such a large number of letters from members of the medical profession inquiring about Senate Bill No. 1096, and House of Representatives Bill No. 603, entitled a bill to fix the status of the Acting Assistant Surgeons, United States Army, who served in the late war, and as I find it difficult to answer the large number of letters I have received asking information about it, I trust you will permit me to reply to them through the Medical Record.

Accompanied by Drs. Henry A. Robbins, Past Medical Director G. A. R. Department of the Potomac, and Henry E. Woodbury, I called on the Secretary of War, General Redfield Proctor, who assured us that the bill appeared unobjectionable; we called to see the Assistant Secretary of War, General Grant, who informed us that he was well acquainted with some of our corps, and that they were "very good men, indeed." We called at the Surgeon-General's office, and, although not having had the pleasure of meeting Surgeon-General Moore, we met Dr. Greenleaf, Surgeon, United States Army, who regretted the absence of the Surgeon-General, but assured us that the Surgeon-General and all the surgeons of the army were friendly to the bill, and that there was not a surgeon or assistant surgeon in the army, who are now serving, that was not an acting assistant surgeon.

We called on the Military Committee of the House of Representatives and explained our case. We were very friendly received by the members, and the following telegram will show the amount of friendship and interest shown us, viz.: "Washington, D. C., April 22d. John T. Nagle, 300 Mulberry Street, New York. Military committee reported a substitute for your bill to-day. It grants substantially all you want. E. J. Dunphy."

Congressmen Dunphy, Cummings, Spinola, Turner (Iceman), of this city, General Post, of Illinois, McAdoo and Geissenhainer, of New Jersey, and several others, we had the pleasure of meeting, and after explaining the bill, they took quite an interest in its passage. The only members of the Committee on Military Affairs of the Senate we met were Senator Davis, of Minnesota, and General Manderson, of Nebraska. Senator Davis unhesitatingly stated that he would vote for it, and General Manderson stated also that he would vote for it. We failed to meet General Hawley, the chairman of the Senate Committee on Military Affairs, as he was attending a meeting of the Loyal Legion, at Philadelphia. We were very pleasantly received by Surgeons Greenleaf, Billings, and Matthews, United States Army, and by several Congressmen and United States Senators in addition to those above mentioned. The original Senate Bill No. 1096, which was printed in the Medical Record on February 1, with slight modification, appears to be in a fair way of passing, and I think that with a little effort on the part of those interested, there will not be much doubt of its passing both houses. Very respectfully yours,

John T. Nagle, M.D.

April 23, 1890.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 20 to April 26, 1890.

La Garde, Louis A., Captain and Assistant Surgeon. Upon surgeon's certificate of disability leave of absence for twenty-three days, on account of sickness, granted, in extension of leave of absence for seven days granted him by order No. 70, Fort Assinniboin, Mont., with permission to apply to the Adjutant-General of the Army for an extension of one month on surgeon's certificate of disability. S. O. 43, par. 4, Department of Dakota. April 14, 1890.

Raymond, Henry I., Captain and Assistant Surgeon, Newport Barracks, Ky. Granted leave of absence for twenty five days, to commence on or about May 2, 1890. S. O. 91, par. 5, Division of the Atlantic, April 19, 1890.

Kilbourne, Henry S., Captain and Assistant Surgeon. By direction of the Secretary of War, transferred from Vancouver Barracks, Wash., to Willet's Point, N. Y. S. O. 93, par. 1, A. G. O., April 21, 1890.

Gray, William W., Captain and Assistant Surgeon. By direction of the Secretary of War, transferred from Fort Maginnis, Mont., to Fort Sherman, Idaho. S. O. 93, par. 1, A. G. O., April 21, 1890.

Banister, John M., Captain and Assistant Surgeon. By direction of the Secretary of War, transferred from Fort Sherman, Idaho, to Fort Stanton, N. M. S. O. 93, par. 1, A. G. O., April 21, 1890.

White, Robert H., Major and Surgeon, now on duty at Fort Myer, Va. By direction of the Secretary of War, will report in person to the Superintendent of the U. S. Military Academy, West Point, N. Y., for temporary duty as post-surgeon during the absence of Major Henry McElderry, Surgeon, as a member of the Army Medical Board, New York City. Upon the return of Major McElderry to duty at West Point, Major White will return to his proper station. Par. 4, S. O. 94, Headquarters of the Army, A. G. O., April 22, 1890.

Official List of Changes in the Medical Corps of the United States Navy for the week ending April 26, 1890.

Scofield, W. K. Commissioned a Medical Director from February 8, 1890.

McMurtrie, Daniel. Commissioned a Medical Inspector from February 8, 1890.

Bogert, E. S. Commissioned an Assistant Surgeon from April 16, 1890.

Spratling, L. W. Commissioned an Assistant Surgeon from April 16, 1890.

Martin, H. M., Surgeon. Reported his return home and granted sick leave.

Woolverton, T., Medical Inspector. Detached from Navy Yard, Washington, D. C., and wait orders.

Beyer, H. G., Passed Assistant Surgeon. Ordered to delay reporting on board the Yantic until further instructed.

Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service, for the two weeks ended April 19, 1890.

Fessenden, C. S. D., Surgeon. To proceed to Marion, Ky., on special duty. April 16, 1890.

Guiteras, G. M., Assistant Surgeon. To report to the Superintendent of Immigration, New York, for special duty. April 12, 1890.

Bailhache, P. H., Surgeon. Detailed as chairman of Board for physical examination of officers of Revenue Marine Service. April 12, 1890. To proceed to Portland, Ore., Tacoma, Seattle, and Port Townsend, Wash., as inspector. April 16, 1890.

Hutton, W. H. H., Surgeon. Detailed as chairman of Board for physical examination of officers of Revenue Marine Service. April 10, 1890.

Long, W. H., Surgeon. To proceed to Marion, Ky., on special duty, relieving Surgeon Fessenden. April 18, 1890.

Kalloch, P. C., Passed Assistant Surgeon. Detailed as recorder of Board for the physical examination of officers of Revenue Marine Service. April 12, 1890.

Magruder, G. M., Assistant Surgeon. Detailed as recorder of Board for physical examination of officers of Revenue Marine Service. April 10, 1890.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 26, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	8	2
Scarlet fever	76	7
Cerebro-spinal meningitis	1	3
Measles	312	32
Diphtheria	120	29
Small-pox	0	0
Varicella	7	0
Cholera	0	0

An Advance in Microscopic Objectives.—At the meeting of the Royal Microscopical Society of England, recently, it was announced that Dr. E. Abbe, of Jena, had presented to the Society one of the new apochromatic one-tenth microscope objectives recently produced at Zeiss's optical works, Jena, under Dr. Abbe's superintendence. The speciality of the new objective is that the aperture is the highest hitherto attained, being designated of 1.6 N.A., whereas the highest point previously reached by Dr. Zeiss was 1.4 N.A., so that the clear gain of aperture is twenty per cent. It is understood that the new construction embodies the use of fluorite in place of crown glass in one or more lenses of the combination, by which a higher degree of achromatism is attained than that of ordinary achromatic objectives. The new objectives are hence designated "apochromatic," and their employment in photomicrography has demonstrated their great practical superiority over objectives of ordinary "achromatic" construction.

Doctors' Fees.—The editor of *Truth* has published the following very sensible observations on doctors' fees: "It is a source of constant regret to me that I cannot agree with all my correspondents. I trust, however, that none of them will ever think the worse of me for failing to fall in with their views. Here, for instance, is a gentleman who invites me to administer a rebuke to an East End doctor, who figured at a recent inquest. The offence was this: 'On being called to the deceased man, who had met with a bad accident, the doctor stated that his fee was 2s. 6d. He was informed that the money would not be forthcoming till later in the day. Thereupon he retired, and the patient was taken to the hospital, where he died.' Now, it so happens that in this case the doctor's refusal to attend was shown to have in no way hastened the man's death. Apart, however, from that consideration, how can the gentleman be blamed? An East End medical practitioner is presumably not practis-

ing as a philanthropist, but earning a very modest livelihood by very hard work. It is just as necessary for him to refuse to give advice gratis as it is for a baker to refuse to give bread to every starving man who may look in at his window. What I would suggest is that, in cases where medical assistance is urgently required, and the patient is too poor to pay for it, the doctor should be allowed afterward to recover his fee from the parish."

Vaccinating against the Poison Ivy.—As the summer season approaches and *rhus toxicodendron* begins to thrive, there is a large number of persons who will take an interest in the statement that an immunity against this plant can be secured. At least it has been done in one instance, related by Dr. John Aulde in the *New York Medical Journal*. He says that Dr. George Kirkpatrick, of La Harpe, Ill., took by mistake a good swallow of the tincture, and in order to counteract the effect of the poison, large doses of olive-oil were administered, and along with it about ten grains of carbonate of sodium. No immediate unpleasant effects were observed until the second day thereafter, when it was found that there was complete desquamation of the cuticle, and since that time he is proof against the poison of the plant.

Do Doctors Catch Infectious Diseases?—An idea prevails that physicians largely escape infectious diseases to which they are exposed, to an extent for which sanitary precautions do not wholly account; in other words, that there is something mysterious and unexplained about it. The fact is that they do not escape. Death-rate comparisons show that deaths among physicians from infectious diseases are much above the normal, as determined from life insurance statistics, while the death-rate among clergymen from the same causes is very much below it.

Circumcision and Heredity.—In connection with the subject of inherited malformations recently referred to in the MEDICAL RECORD we may cite the following, which appeared some months ago in the New York *Medical Journal*. Dr. Levy, a dentist of Stettin, has written to the Editor of the *Archiv für pathologische Anatomie una Physiologie und für klinische Medicin*, an account of some occurrences in his own family that have a bearing, he thinks, on a question raised by Professor Weismann at the sixty-first *Versammlung deutscher Naturforscher und Aerzte*—that of the hereditary transmission of acquired peculiarities, such as the lack of a foreskin in Jews. He states that, like his father before him, he was born without a foreskin—as he expresses it, "regelrecht beschnitten"—furthermore, that this was the case with his four brothers also, who died in childhood. An occasional natural Apella is to be met with among Gentiles, but this, of course, raises no question of heredity; such a group of them as Dr. Levy's communication mentions is a different matter, however, although not a very convincing evidence of evolution.

Abdominal Surgery in Cuba.—At the Medical Congress recently held at Havana, Dr. Barrena presented a communication containing statistics of abdominal surgery in Cuba up to that date. The operators were Drs. Cabrera Saavedra, Plasencia, Casuso, Horstmann, Menocal, R. Tovor, and himself. The following are the figures given by Dr. Barrena: Ovariotomies, 39, with 27 cures and 12 deaths; hysterectomies, 11 cured with 2 deaths; myomotomies, 3, all cured; exploratory incision, 4, with 3 deaths; salpingotomies, 3, all cured; vaginal hysterectomy, 1, fatal; ligature of the Fallopian tubes, 1, cured; total 62 operations, with 37 cures and 25 deaths, showing a mortality of more than forty per cent. One of the speakers in the discussion which followed said such statistics testified against the operators more than against the operations. He expressed gratification that what he called the *furor operatorio* was subsiding in Cuba.

Vivisection at Clark University.—Mr. George T. Angell, president of the Massachusetts Society for the Prevention of Cruelty to Animals, has had his agents, at different times, investigate the charges made that the vivisection at Clark University, in Worcester, was cruel and unlawful. They report that since the opening of the university seventeen dogs and a less number of cats have been operated upon, but not in a single instance without the use of anæsthetics. No operation has been performed to prove any fact before established. All the animals, except in very few instances, have been despatched as soon as the operations were performed, and before they became conscious.

A Case of Necrosis of the Jaw, Following Measles.—Necrosis of the jaw occurs after eruptive and other fevers, especially after scarlatina, and is more frequently seen in children from three to eight years old, a period at which these parts must supply nourishment both for the permanent and for the deciduous teeth. It appears usually as the fever subsides, and is ushered in by pain and swelling about some part of the gums, which leads to suppuration and death of the bone. This necrosis does not, as a rule, involve the body of the bone, but is limited to the alveolus. Both jaws are equally liable to the affection. If a gap is left permanently in the jaw, the opposing jaw may grow so as to fill up the deficiency. Thus, in a case recorded by Bryant, the lower jaw grew nearly an inch higher than natural to compensate for the loss of substance in the upper jaw. In the "Transactions of the Iowa State Medical Society," vol. vii., Dr. McCarthy relates a case which occurred in his practice in 1887. He was called to see a boy, eight years old, of a healthy family, who had broken out with measles the day before. As the case was mild he gave no drugs, but asked to be called if complications arose. Three days later he found the patient with severe pain in the left ear and jaw, swelling and redness of the jaw, and capillary bronchitis well marked in both lungs. A laxative was given, with quinine, carbonate of ammonia, and whiskey, and hot dry applications were made to the jaw. During the next four days all the teeth of the left upper jaw were removed, as they had become loose and were protruding from the jaw. There was a very foul odor, and the scanty pus was swallowed by the patient, except so much as was removed by syringing with bichloride solution, 1 to 2,000. The fever now decreased from 103°F. to 99° F., the boy feeling better. A week later a piece of loose bone, supposed to be the left upper alveolar process, was taken away, and iodide of potassium was given with tonics. Five weeks afterward, as the local disease continued, in spite of improvement in the general health, chloroform was given and, by the aid of forceps, "the left superior maxillary bone was removed from the median line to the zygomatic fossa, including all the alveolar process, and up to the infra orbital foramen on the facial surface and to the palate bone on the internal surface, leaving only the orbital surface. The palate bone was left intact." Three weeks later the alveolar process of the lower jaw on the left side was removed with the loose teeth attached to it, leaving only the last bicuspid and the bit of bone in which it was inserted. At the end of the third month after this operation the boy presented no deformity of the face, except a drawing of the lips toward the left when he tried to laugh or whistle. The superior maxillary had been reproduced and three teeth were making their appearance—an incisor, a canine, and a bicuspid. In the lower jaw all the old teeth that were removed had been replaced by new ones, and the old bicuspid still remained. Dr. McCarthy states that although cases are recorded where bony structures (especially the inferior maxillary) have been reproduced, he finds no instances in which teeth have been reproduced in the upper jaw, nor where the superior maxillary has been replaced. His case is remarkable on account of the rapid destruction and separation of the parts, their almost complete reproduction, and the absence of any marked deformity.

Madrid has one physician to every 700 of its inhabitants.

Notification of Vital Statistics. — At the meeting of the New York City Board of Health, recently, a resolution that the counsel prosecute persons who have failed to report births, marriages, and deaths within the proper time was adopted.

A Mother at Thirteen.—A precocious girl of thirteen years and eight months is reported to have given birth to a male child recently in the Vienna Foundling Hospital. The infant was very small, weighing less than three pounds, and although born alive, it is so weak that the doctors hold out but little hope to the mother that she will succeed in rearing him.

The Physiology of Taste.—The localization of the different forms of taste sensations is a subject which is usually cursorily passed over in text-books, with the statements that the posterior third, the tip, and sides of the tongue only are sensitive, that sweet substances are best perceived by the tip, bitter ones at the back, and so on. In the *Centralblatt für Med. Wissen.* is an abstract of interesting observations by Oehrwall, who, by the aid of a lens, stimulated the individual papillæ by means of a fine brush dipped in solutions of sugar, quinine, acetic acid, and salt. He found that, as had before been observed, the circumvallate papillæ were particularly sensitive, but that on the sides and tip the fungiform papillæ only were sensitive. He estimated that in the whole tongue there were 350 to 400 of these papillæ, of which he found 125 only to respond to stimuli. Many of them appeared to be excited by all four of the substances employed, but in other cases papillæ were found to respond to one form of stimulus but not to another. Thus nineteen per cent. responded to acetic acid, but not to sugar; twenty-four per cent. which were sensitive to acid were unaffected by quinine, while fifteen per cent. which recognized sugar did not respond at all to the application of quinine. All of the papillæ were sensitive to touch, pain, heat, and cold. When stimulated by a mild faradic current, an acid taste only was excited. He confirmed the observations of older authors, that most of the anterior two-thirds of the dorsum of the tongue was devoid of gustatory papillæ.—*The Lancet.*

The Employment of Hypnotism for Physiological Investigation.—Dr. Segal is reported to have endeavored, by hypnotizing two female subjects, to decide the question whether there is a single oculo-motor centre for both eyes, or whether each eye has its own special centre. The right eyelid of the hypnotized individuals was raised, and it was suggested to them that they should keep the right eye immovable, and when this suggestion had been complied with it was further suggested that the left eye should be turned inward and outward. In one of the individuals this was accomplished, but no movements of the left eye in a vertical direction could be obtained, and no binocular divergence could be produced. The second patient could turn the left eye up or down and inward or outward, and here again no binocular divergence was perceived. Experiments on the reaction of the pupils were further tried on the first and on a third patient, by telling them that all around was black, and consequently nothing could be seen; this caused the pupils to dilate. Similarly, they contracted when it was suggested that the darkness had passed away, and that the sun now shone. Dr. Segal concludes from his experiments that each eye has its own oculo-motor centre, just as the other ocular nerves have, but that the two, in consequence of continual associated movement, are very closely linked to one another.

Barristers and Medical Charges.—The *Newcastle Chronicle* expresses surprise at counsel, Mr. Walton, objecting to the charges of Dr. Crosby for a fortnight's close attendance in a case of fatal injuries from a tramcar, some of the visits being at night, and the wounds requiring dressing. The injuries included, we are informed, two fractures of the arm and a compound fracture of the foot. Twenty-eight visits were paid, and the charge was £21. Our contemporary thinks that if a barrister had to be called out at night he would be apt to require both larger fees and payment beforehand. We think so too. We need add nothing to our contemporary's excellent presentation of the case. We cannot withhold his pointed and brief contrast of the case of barristers and doctors. "As a rule, barristers have their fee beforehand; in many cases doctors are never paid at all. It has even sometimes happened that eminent counsel have pocketed fees for cases in which they have never appeared. Doctors have no such luck." Mr. Walton will perhaps be a little more careful when he has next to deal with medical fees in grave cases.—*The Lancet.*

Disease of the Heart Resulting from Emotional Causes.—Dr. Robert Lee writes as follows in the *Lancet*: "In the discussion which not long ago occurred at the Royal Medical and Chirurgical Society on the connection between chorea and rheumatism, a question of great importance was raised which has not yet received the attention it deserves: Is it possible for emotional disturbances, for fright, anxiety, or worry to cause disease of the heart? The question is one of rather wide interest, because the pathologist, the metaphysician, and especially the clinical observer, are equally entitled to deal with it. It will probably occur to those who have studied the etiology of Graves' disease that we should be prepared to find in this class of cases some evidence that disorder of the circulatory system may arise from purely emotional disturbance. A case was under my care in the year 1882, which I am induced to publish as contributing to the interesting question above referred to. The patient had been nurse in a family with which I was well acquainted. She was twenty years of age, a well-grown girl, with good family antecedents, and without history of any disease possibly effecting the heart. For eighteen months she had been gradually losing health and strength, and developing the symptoms from which she was suffering when I saw her. These were marked debility, slight anæmia, and troublesome palpitation of the heart. She could not walk without distress from breath-shortness; she had pains in the thighs and some swelling and induration of the tissues, such as to suggest phlebitis of the saphena or deep femoral veins. The cardiac pulsations were generally 140 per minute; they would rise to 150 if she got up or if she were the least excited. After rest in bed and treatment, pulsations diminished to 120 for a few days, but returned to the higher number. Thus she continued for two months, with little if any improvement in respect of the condition of the heart, though relieved of local pains and feeling generally somewhat stronger. Digitalis did not have any effect in this case, but small doses of opium at first quieted the heart. The cause which was assigned by the patient for this condition of ill-health was the following; and by evidence from other sources the absolute truth of her statement was confirmed. One day, when sitting in the nursery with the children, their father came into the room in a state of mental derangement, and seizing hold of the youngest, an infant, acted with the apparent intention of throwing it out of the window. The girl was so overcome by terror that, as she told me, she was unable to move or speak. From this occurrence she dated her illness. The case resembled in many respects one of Graves' disease, with the exception that there was no protuberance of the eye-balls or enlargement of the thyroid. The heart's action was regular, though rapid; the pulsation strong, and evident to the eye. There was also increased pulsation in the large arteries in the neck. There was a faint systolic bruit heard over the apex area. At the end of two months the patient returned home, and I have not heard what course the malady took since that time. It must have been observed that irregularity and increased pulsation of the heart frequently occur in children suffering from chorea, when there is no association of chorea with rheumatism, and no evidence of valvular affection.

It seems probable that this peculiar symptom of increased cardiac pulsation is due rather to derangement of the nervous system of the heart than to a distinct organic lesion of the valvular, muscular, or other tissues. Although it may be impossible in our present state of pathological knowledge to give any explanation of the nature of the morbid condition of the nervous system of the heart which is indicated by increased pulsation or irregularity of action, and which is attributed to emotional disturbance, it is well to admit the clinical evidence of its possibility; and generally, though such derangement of the heart's action may be of temporary duration, occasionally, though rarely, it may be of more serious and permanent character, as in the case briefly related above."

Pineapple-juice is the latest discovered domestic remedy for diphtheria. It is said to be used with great and unfailing success by the negroes of Louisiana and other parts of the South.

A Rare Complication of Influenza.—Dr. W. F. Lippitt, Jr., of Charlestown, W. Va., writes that he saw recently a case of influenza accompanied by acute dacryocystitis with very great chemosis of one eye. The treatment of the case was by antifebrine and inhalations of steam, and the eye symptoms disappeared without any special local treatment.

Was the Poison in the Milk?—Dr. Timothy E. Wilcox, of the United States Army, writes from Fort Niobrara as follows: "A patient of mine suffered from an attack of facial erysipelas during her last pregnancy. She was delivered of a healthy male child which she nursed for two months, being then obliged to desist on account of the milk being unsuited to her child. She drew from her breast some of the milk and set it aside in a glass. A child, three years of age, drank it, and nine days thereafter was attacked with erysipelas of the face as its mother had been. Was this infection or coincidence?"

The Ninth German Congress for Internal Medicine was held last month in Vienna, and not at Wiesbaden as hitherto. Discussions took place on influenza, treatment of empyema, and treatment of chronic nephritis. Among the papers read were the following: Dr. Unna, of Hamburg, on "Physiology of the Skin;" Dr. Mosler, of Greifswald, on "Pemphigus;" Dr. E. Gans, of Carlsbad, on the "Gastric Functions in Diabetes Mellitus;" Dr. Fürbringer, of Berlin, on "Clinical Contributions to the Forms of Osteitis of Typhoid Origin;" Dr. Stadelmann, of Dorpat, on the "Action of Alkalies upon Tissue Metabolism;" Dr. v. Liebig, of Reichenhall, on the "Mountain Disease;" Dr. v. Frey, of Leipsic, on the "Relation between Forms of Pulse and Valve Closure;" Dr. Schott, of Nauheim, on "Forms of Acute Overstrain of the Heart and their Treatment;" Dr. Sternberg, of Vienna, on "Tendon Reflexes;" Dr. H. Curschmann, of Leipsic, on the "Pathology of Floating Kidney;" Dr. G. Cornet, of Berlin, on "Tuberculosis."

A Leper in Philadelphia.—A Chinaman was admitted to a hospital in Philadelphia a few days ago, suffering, it was supposed, from facial erysipelas. It was soon discovered, however, that he had leprosy. He was at once removed to the Municipal Hospital, and now the health authorities are wondering what they can do with him.

The Cause of Cheapness of Quinine.—The present very low price of quinine is due, it is said, to the large amount of cinchona sent out from Ceylon. When coffee, which for a long time was the staple production of that colony, began to fail because of a disease which attacked the trees, cinchona was largely substituted by the planters for the failing staple. In a short time, however, the cinchona began to fail from depreciation in quality; the Ceylon planters turned their attention to tea with so much energy that they cut down their cinchona trees to make way for tea-bushes, and, not being able to hold their bark, they sold it in the London market for what it would fetch. The result has been an enormous fall in price, so that the bark has been obtainable at less than the cost of production, and quinine has fallen to a figure far below anything previously heard of. The export from Java has also increased in recent years. South American bark, which a few years ago was the only source of quinine, has practically been driven out of the market, and the world has been drawing its supplies of quinine from the British and Dutch colonies in Asia.

Physical Culture in the Schools.—At a recent meeting of the Principals' Association, of Brooklyn, it was resolved to request the Superintendent of Public Instruction to recommend in his next annual report to the Board of Education that some approved system of physical culture be taught in the public schools.

The Oneida County (N. Y.) Medical Society held its regular quarterly meeting in Utica on April 8th. Dr. Chas. G. Wagner reported a successful case of trephining in a negro with hemiplegia. After the evacuation of about six ounces of fluid the paralysis gradually disappeared.

The New Jersey Board of Medical Examiners.—The bill providing for a State board of examiners in medicine passed the New Jersey Senate recently. In its final shape it provides that the State board shall consist of nine physicians—five regulars, three homœopaths, and one eclectic. A student shall be examined in therapeutics and materia medica by the members of the board of his own school only, but no applicant shall be admitted to practice except upon unanimous vote of the board. The bill will have to come back to the House now, so that the Assembly may concur in the slight amendments of the Senate.

San Francisco has at present two city physicians, and no one seems to know which of the two is legally appointed. One was appointed nine months ago, and claims that he has not resigned nor received any notice of dismissal. Recently another physician was appointed to the same position, and now the city's poor and the prisoners receive double attention.

The Yale Medical School.—Circulars have been sent to the alumni of the Medical Department of Yale University, asking for contributions to a fund for obtaining a $25,000 building suited to laboratory work, and for remodelling the old building, and buying microscopes and other instruments at a cost of about five thousand dollars.

The American Association for the Advancement of Physical Education held its fifth annual meeting in Boston on March 4th and 5th. Several papers on subjects relating to physical education and anthropometry were read. Dr. D. A. Sargent was elected president for the ensuing year.

Doctors as Dispensers of Spirits.—The Iowa Legislature has just enacted a Pharmacy Law which, it is said, contains a provision that will make whiskey freer in Iowa than it has been under prohibition. It confers upon physicians the right to dispense liquor, and places upon them no restraint whatever. They do not need a permit, like the druggists, nor is there any supervision of their manner of prescribing in the sales they make. There are about five thousand doctors in the State, and the demand for diplomas is likely to increase to an unprecedented extent.

To Improve the Sanitary Condition of the Schools.—The Bridgeport, Conn., Medical Association has issued a circular to the teachers of the various public schools, asking a series of questions bearing on the sanitary and hygienic condition of the school buildings, in order to determine how much of the physical deterioration of the teachers and pupils, if any exists, is due to their surroundings.

OBSERVATIONS ON THE CAISSON OR TUNNEL DISEASE.

With Notes on Nine Cases which occurred at the Engineering Works known as the Hudson River Tunnel.

By J. LEONARD CORNING, M.A., M.D.,

NEW YORK.

CONSULTANT IN NERVOUS DISEASES TO ST. FRANCIS HOSPITAL, JERSEY CITY; THE HACKENSACK HOSPITAL, N. J., ETC.

As one of the New York members of the board of consultants of St. Francis Hospital, Jersey City, I have recently had the rare opportunity of studying a number of cases of that remarkable affection known as the "Caisson" or "Tunnel Disease." The cases in question were all conveyed to the medical wards of St. Francis, where they remained until sufficiently recovered to leave the hospital. It was during the service of Dr. William Perry Watson, the attending physician, that I was able to see these cases at frequent intervals, and it gives me great pleasure to express publicly the obligations which I am under for the numerous courtesies extended to me by Dr. Watson in the wards over which he presides.

General Conception of the Disease.—The caisson or tunnel disease is an affection of the spinal cord, due to a sudden transition from a relatively high atmospheric pressure to one much lower. Hence, those who work in caissons, or submerged tunnels, under an external pressure of two atmospheres or more, are liable to be attacked by the disease shortly after leaving the tunnel. The seizure never, however, occurs while the subject is in the caisson, or, in other words, while he remains under pressure.

The chief clinical features of the disease are pain, which may be relatively mild, as when confined to some portion of one or more extremities, or of frightful intensity, as when it appears in the ears, knees, back, or abdomen; anæsthesia and paralysis, usually of paraplegic type; bladder symptoms, assuming the form of retention or incontinence; and, more rarely, rectal disturbances (usually incontinence).

In cases of moderate severity the patient usually recovers in a few days or weeks, while in the very severe ones he gradually loses strength and eventually succumbs. Besides these extreme phases of the disease there is an intermediate class of cases in which the patient, though grievously ill, may recover sufficiently to get about with sticks, or even unassisted. In these cases recovery is, however, but partial, the subject remaining more or less feeble and hyperæsthetic during the remainder of his life.

Since Triger, a French engineer, first described the characteristic pains of the caisson disease in 1841, the affection has several times received attention at the hands of European physicians who were in a position to observe it in connection with the diving-bell, bridge-building, mining, and other operations requiring the use of compressed air.

A list of the literature pertaining to these historical matters will be found at the end of this paper.

In the United States several opportunities of studying the disease have occurred during the last few years. The most noteworthy of such occasions were the construction of the St. Louis Bridge in 1868, the Brooklyn Bridge at New York about the same time, and the Hudson River Tunnel at a later date.

Dr. A. Jaminet[1] was in charge at the St. Louis Bridge, while Dr. Andrew H. Smith[2] attended at the Brooklyn Bridge. Both these gentlemen published most interesting papers, embodying their personal knowledge of the "Caisson Disease" as it occurred in connection with these colossal undertakings. My own opportunities of studying the disease, as it occurred at the Hudson River Tunnel, New York, have already been mentioned.

Before entering upon a more extended consideration of the subject, a brief account of the works at the Hudson River Tunnel, with a description of the manner of conducting the extensive engineering operations involved, may prove both interesting and instructive, as affording a more complete insight into the genesis of the disease.

A Brief Description of the Hudson River Tunnel and the Pneumatic and Other Devices Employed in its Construction.—The object of the Hudson River Tunnel is to afford passage for railway trains under that portion of the stream which separates New York from Jersey City. More than twenty years ago the distinguished engineer, Mr. D. C. Haskins, proposed to carry out the enterprise substantially in accordance with the present plans. The undertaking has, however, been exposed to great vicissitudes—accidents, financial difficulties, and legal complications having conspired to delay and imperil the work at every turn. It would be foreign to the objects of the present paper were a description of these hardships of

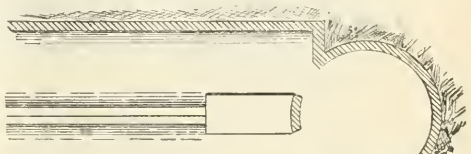

FIG. 1.—Diagram showing North and South Tunnel and Shaft.

the tunnel company to be given in detail; I shall therefore merely recall one terrible event in the history of the enterprise. On July 21, 1880, a portion of the tunnel collapsed; the water rushed in, and the works were completely flooded. Twenty men, in the employ of the company, were in the tunnel at the time. When the waters entered a mad rush was made for the locks; the doors of these structures could not, however, be opened on account of the great air-pressure, and all perished miserably.

The method of working has varied somewhat from time to time, but I shall only describe that which is at present in vogue.

On each side of the river vertical shafts have been sunk, that on the west shore being sixty-five feet deep and thirty-five feet in diameter. These shafts constitute the points of departure for two tunnels (Fig. 1). One of these tunnels is known as the "North Tunnel," while that which is below it is called the "South Tunnel."

[1] Jaminet, A.: Physical Effects of Compressed Air, and of the Causes of Pathological Symptoms produced on Man by Increased Atmospheric Pressure. St. Louis. 1871.

[2] Smith, A. H.: The Effects of High Atmospheric Pressure, including the Caisson Disease. Brooklyn. 1873.

In following out the plans of the engineer, a small tube known as the "pilot" is first advanced thirty feet or more into the silt, which constitutes the bulk of the material to be taken out. The pilot is but six feet in diameter and is composed of quarter-inch iron plates. Its function is to support the wooden braces which radiate from its periphery, which, in their turn, sustain the steel shell composing the outer stratum of the main tunnel (Fig. 2). As the pilot advances masons follow in its

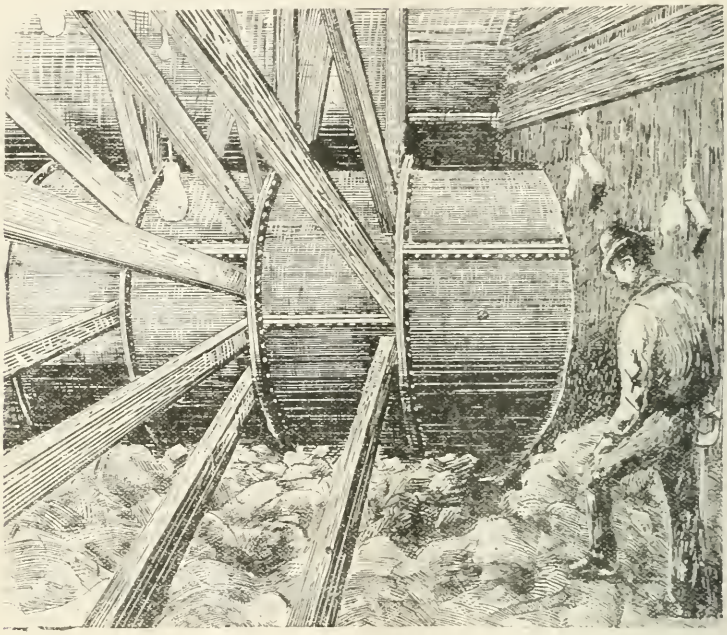

Fig. 2.—Diagram showing the "Pilot," the Sustaining Beams, the Breast of Tunnel, and General Mode of Working.

track, and build within the steel shell a lining of brick two and one-half feet thick. In order to prevent air-leakage the surface of the brick-work is covered with a thin stratum of cement mortar. The tunnels are at the present time eighteen feet high and sixteen wide inside. The distance of the tunnel line from Hudson Street, Jersey City, to the foot of Morton Street, New York, is five thousand five hundred feet, to which must be added the extensive terminals on both sides of the river (Fig. 3). On the New Jersey side, nearly two thousand feet of the north tunnel have already been completed; while the south tunnel of the same side has been advanced about six hundred feet. The work accomplished on the New York

great solidity has been constructed; it is composed of a brick wall four feet thick, to which additional strength is given by timber braces. The air-lock proper consists of an iron cylinder sixteen feet long and six feet in diameter, which projects through and is built into the bulkhead (Fig. 4). At each end of the cylinder is a door, which opens in the direction of the heading. Strong windows of plate-glass set in the iron-work enable the laborers on both sides to communicate with each other by the aid of messages written upon a slate. In front of this structure, which constitutes the first air-lock, an atmospheric pressure of twenty-five pounds to the square inch is maintained by the aid of powerful air-pumps, situated above ground.

The second air-lock is located but a short distance from the heading; its arrangement is much like that of the first, so that a description of its mechanical details is unnecessary. The atmospheric pressure in front of the second bulkhead is maintained at from thirty-two to thirty-four pounds to the square inch, as shown by the gauges at the air-pumps. It is in this atmosphere that the heavy work of excavation and construction is performed.

Fig. 3.—Showing Longitudinal Section of Tunnel between Bulkheads.

side is by no means so extensive, very little more than a beginning having been made at the south tunnel, while of its fellow but one hundred and fifty feet have been completed. Little or nothing is being done on that side at present.

The work on the New Jersey side is, therefore, that which possesses the most interest, and this is specially true of the north tunnel. The pneumatic arrangements in this tunnel present some excellent features. Nearly twelve hundred feet from the entrance a bulkhead of

and it is on emerging thence that the workman experiences that portentous depression of the vital functions which so often culminates in an attack of what he calls the "Bends," or, as we know it, the "Caisson Disease."

The manner of operating the air-lock is quite simple. The door facing the tunnel entrance is first opened, and, the visitor having entered the tubular chamber, it is then closed. Meanwhile the inner door—that which faces the heading—is of course closed, so that those in the lock are hermetically incarcerated. The compressed air

of the tunnel is then gradually admitted through a valve until the density of the atmosphere of the lock corresponds with that of the tunnel (Fig. 5). This process of "locking in," as it is called, is accomplished very gradually, ten minutes or more being consumed in the operation. This deliberation is specially necessary in the case of those who are about to enter the tunnel for the first time. In coming out the process is of course reversed; for, when both doors of the lock are closed, the latter contains condensed air, and this is allowed to blow off into the open tunnel through a valve.

It is evidently a matter of the first importance that the pressure should be uniform in works of this kind. This is attained by the aid of a very perfect set of air-compressors, run by engines of special construction, in conjunction with an automatic fuel regulator, which, while extremely economical, serves also to maintain a definite steam-pressure. These devices, in conjunction with an effective set of gauges enable the engineer in charge to regulate the pressure with great nicety.

When in active operation the work is carried on day and night, to accomplish which three sets of workmen are employed. The duration of the shifts has varied considerably during the prosecution of the work, according to the amount of pressure employed. In the beginning the pressure was relatively low — from eighteen to twenty pounds to the square inch—and it was therefore possible for one set of men to remain at work for six hours or more. Under the existing high pressure, however, this is no longer possible, the laborers being obliged to adopt short shifts of three or four hours.

The mode of construction employed at the Hudson River Tunnel differs from that adopted in previous enterprises of the kind, in that compressed air is used to afford partial support to the earth at the heading and to keep out the water. Whether this is the most judicious manner of operating horizontal works has been questioned; though, as applied to vertical operations, as in sinking caissons for the foundations of bridge piers, its efficacy has long since been abundantly proven.

In concluding this brief account of what is certainly a most extraordinary example of bold engineering, I desire to express my sincere acknowledgments to Mr. C. A. Haskins, superintendent of the works at the tunnel, for conducting me about, and informing me with much detail as to the various scientific features of this remarkable undertaking.

Manifestations of the Tunnel Disease.—Having familiarized ourselves somewhat with the peculiar conditions which surround those who are prospective victims of the caisson or tunnel disease, we are now in a position to study with advantage the invasion and course of this extraordinary affection.

Though somewhat protean in its manifestations there is one symptom which is common to all cases—pain. However, this pain exhibits a predilection for certain regions of the body, notably for the knees, the elbows, the epigastrium, the deltoid, the lumbar muscles, and the ears.

As previously observed at the beginning of this paper, the pains do not come on while the subject is in the condensed atmosphere, but from twenty minutes to half an hour after he has left the tunnel. Let me illustrate the more conventional points of the symptomatology by reviewing a typical case.

A laborer, of German extraction let us say, enters the tunnel, where he continues to labor during the customary shift of four hours. During his sojourn in the highly condensed air he experiences no special inconvenience, but, on the contrary, he affirms that he "never felt better in his life." If we examine him at this time we find his pulse strong and rapid, say from 120 to 140; his skin is warm and moist; he performs such acts a sclimbing and lifting with less difficulty, especially as regards breathing, than under normal atmospheric conditions; and, in a word, all his vital processes seem wonderfully exalted—at least, this is the case for a time. After working in this

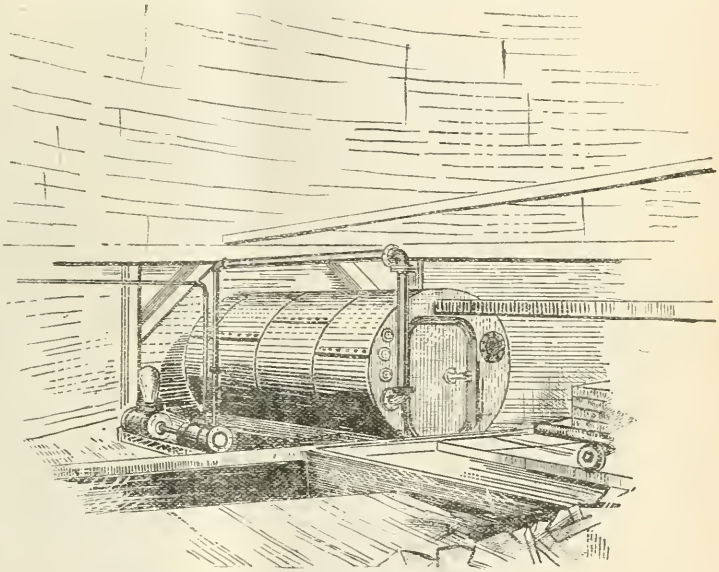

Fig. 4.—External View of Air-lock.

way for three or four hours, however, he begins to feel marked sensations of fatigue. Soon after this, the shift being at an end, he leaves the tunnel in company with the other workmen, due precautions having been taken to "lock out gradually." Let us follow him on his homeward journey. On entering the normal atmosphere once more—or rather, shortly afterward—a remarkable change is observable in our laborer. His skin is cool and covered with a clammy sweat; his pulse, compressible and slightly irregular, has fallen to 60 beats; and he suffers from a sense of prostration, which finds its reflection in a slow and hesitating gait. For half an hour, or less, he wanders on, when suddenly, without the slightest warning, he is seized with pains in the lower limbs of such violence as to cause him to fall to the ground, or sink upon the nearest door-step. An ambulance is summoned; the poor fellow is conveyed to the hospital; and here, while mitigating the most urgent symptom, the pain, we have a rare opportunity of studying a remarkable disease.

The first thing that strikes our attention is the pale skin covered with clammy sweat. The pulse, too, is small, slow, and easily compressible, while the face wears a pinched, haggard, wistful appearance, which is quite characteristic of this early stage of the disease. Of course the pains already alluded to are largely responsible for this anxious look; they are usually of excruciating severity, being often described as "tearing," "burn-

ing," or "sawing." Sometimes they predominate in the knees, at others they are more marked in the abdomen. In some instances they are also felt in the back and arms, more especially in the elbow or shoulder, but these cases are not so common. The advent of the pains, whatever their situation, is often marked by the occurrence of phenomena which may justly be described as prodromic. In quite a number of cases I was told that the patient felt a terrific "buzzing" in the ears, accompanied by other unpleasant auditory sensations shortly before the occurrence of the severe pains in the knees and abdomen. In other cases the first premonition the patient had of impending trouble was a slight pain at the intersection of the deltoid or in the articulation of the jaw or in the elbow.

impairment of both sensation and motion in the lower extremities.

When we thrust needles into the integument of the ankle and thigh, they are not felt; and when we ask the patient to move his legs he cannot do so. The muscular sense, however, sometimes evinces a strange immunity, as may be demonstrated by the appropriate tests, both subjective and objective.

The zone of anæsthesia is somewhat variable in extent and irregular in distribution. Sometimes it extends to the knees, while in other cases it reaches well up the thighs, and I have seen it include the lower portion of the abdomen and more or less of the lumbar region. It is usually higher in front than behind, though not always

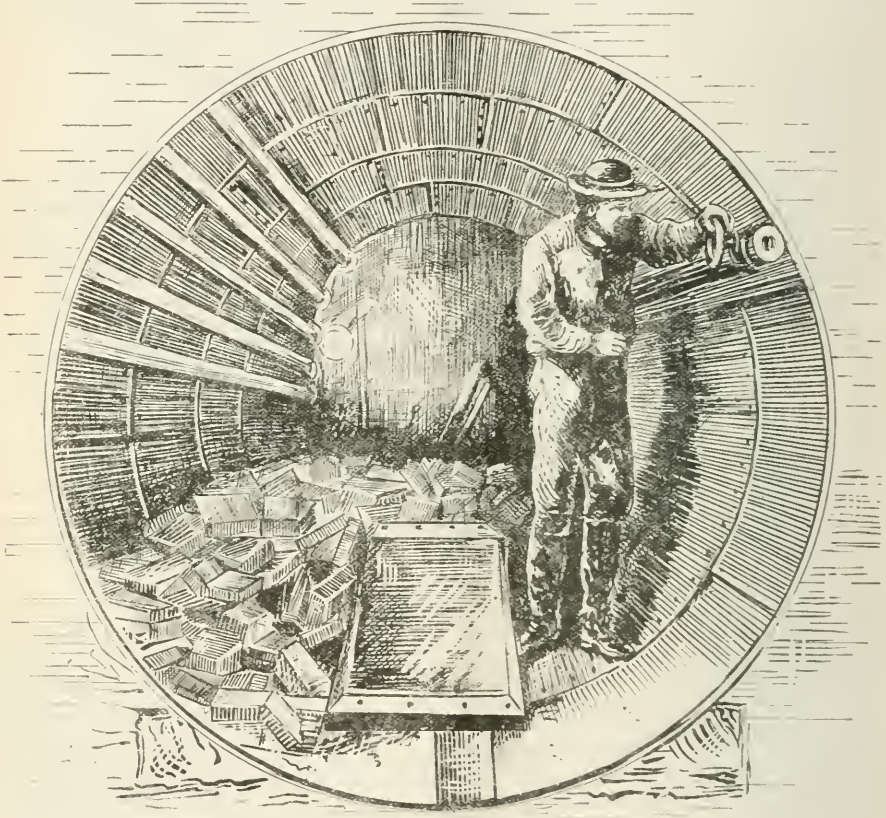

FIG. 5.—Interior View of Air-lock, showing Method of Manipulating Valves.

Sometimes intelligent workmen, who are accustomed to observe the manifestations incident to working in a highly condensed atmosphere, are warned by these and similar phenomena to resort to prompt measures for aborting the attack. They do this in a very simple fashion—in fact, by merely returning to the tunnel, where the compressed air seems to act as an effectual prophylactic.

When recounting adventures of this sort, the men usually speak of having had "a little bend," by which they evidently mean either that they have had some of these unpleasant premonitory symptoms, or that they have really suffered from a mild attack of the disease. Though sensory and motor disturbances of the lower extremities are either absent altogether, or at all events only slightly marked in the milder forms of the disease, the more severe types are characterized by the presence of profound

so, and the entire upper limit is quite irregular in contour and not at all like the comparatively regular line of demarcation found in transverse myelitis or severe traumatism of the cord. As a rule, the region just above the zone of anæsthesia is quite hyperæsthetic, and occasionally sensitive areas may be found encroaching upon the insensitive area; such, at least, is the case when convalescence has set in and the motor and sensory disturbances have begun to abate. There can be no doubt, I believe, that these complex manifestations are due to the irregular distribution of the lesion in the lower segments of the cord.

As may readily be imagined, bladder and rectal symptoms are not uncommon. In the beginning there is vesical paralysis and severe tenesmus; the detrusor fails to act and the water must be drawn with the catheter. The

distress in the bladder is very great at this time, and the patient implores the nurse to use the catheter at frequent intervals. Since the reflex centre for the rectum is situated in the lower part of the spinal cord, in the immediate vicinity of the urinary centre, the subject often experiences difficulty in evacuating the bowels. Cathartics and enemata are, therefore, frequently indicated at this time.

Later, when the symptoms of the disease have begun to subside, the patient is able to pass both water and fæces without much difficulty; and, indeed, he sometimes does this quite unconsciously, owing to the impairment of sensibility in the bladder and rectum, which prevents the mind from being informed as to what is taking place in those viscera.

Trophic disturbances are not uncommon in the severer forms of the caisson disease; these usually assume the form of bed-sores, resembling the malignant type occurring in the course of acute myelitis. A case of this kind was brought to the medical wards under the charge of Dr. Watson, at St. Francis Hospital, Jersey City. Although I did not succeed in getting over to the hospital from New York in time to see this interesting case, Dr. Watson informs me that the slough was most extensive, so much so, in fact, that the man was shorn of a goodly part of his buttocks.

Abnormal fluctuations of temperature are not uncommon. During the extreme prostration which occurs shortly after the advent of the pains, it sometimes declines from ½° to 1° F., whereas in very severe cases—those characterized by paraplegia and paralysis of the bladder and rectum—it may rise 1° F. or more. Whether in such cases we have to do with a secondary myelitis or not remains an open question; analogy would seem, however, to lend support to the supposition.

Though severe cerebral symptoms are relatively rare, they are nevertheless observed in a small percentage of cases. When they do occur, the chances of the patient's recovery are always greatly jeopardized; most cases terminating fatally. An instance of this kind occurred at St. Francis Hospital, the subject, who had labored for some time in the tunnel, dying with symptoms of a typhoid character. I did not have an opportunity of seeing this case, and the knowledge which I have of it is derived from information kindly afforded me by Dr. William Perry Watson, Dr. J. D. McGill, and Dr. W. W. Varick. In fatal cases of this sort the end is without pain, the transition from profound coma to death being almost imperceptible.

Although such cerebral symptoms as these are quite the exception, various minor disturbances of a cognate character are frequently observed. As an illustration of this, patients have frequently told me that they suffered from evanescent attacks of vertigo, headache, and difficulty in talking consecutively (functional aphasia). Dr. Andrew H. Smith also refers to diplopia as a common manifestation, but I have not had the opportunity of observing this symptom.

Course, Duration, Prognosis.—Cases of minor severity usually recover in from one to two weeks, or even less, while those of a graver type require a much longer time before the patient is restored sufficiently to get about.

The prognosis in ordinary cases is good, many of the men going back to work soon after leaving the hospital. The fact that the individual has had an attack affords, however, no immunity; indeed, he is rendered thereby more susceptible, a subsequent seizure being certain to prove more severe than the first. The most severe case which I saw occurred in a man who had already suffered from repeated attacks.

Cases.—The following is a brief synopsis of the cases which I had an opportunity of seeing at St. Francis Hospital:

Case I.—G. F——, Frenchman, formerly occupied as a cook, was induced to accept a position as workman in the tunnel because he failed to secure anything to do elsewhere. He had only entered the tunnel once, remaining there four hours; fifteen minutes after leaving it he was seized with violent pains, first in the elbow and directly afterward in the chest and abdomen.

Simultaneously with the advent of these pains, or shortly afterward, he became aware that he had lost the power of moving his lower limbs, while a peculiar "stiffness" had invaded the arms.

Sensation was quite gone in the legs, but was little or not at all affected in the arms.

In the beginning his water had to be drawn with a catheter, but later he passed it involuntarily.

The patient gives a graphic description of his sufferings, comparing the pains in the limbs to sensations produced by thrusting red-hot needles into the flesh, while those in the chest feel, he says, as though a belt were drawn tightly about him. Both kinds of pain are intermittent, but those in the chest are always followed by a disagreeable sensation of tightness.

For the first five days patient lived on milk almost exclusively; on the sixth day he began to regain sensation and motion in the legs, on the tenth he could stand, and on the fifteenth he could walk about the wards by the aid of a cane. Discharged on the twenty-second day.

Case II.—C. Z——, German workman; occasional drinker; had been at work in the tunnel for some time. After a night of debauch he went to his work in the tunnel, feeling, as he says, "hardly able to raise his hand." In a short time, however, he felt much better and continued to work until relieved by the succeeding shift. On leaving the tunnel he felt very languid, but thought nothing of it, as he had noticed the same thing on former occasions. He had gotten about half-way home, when he was seized with a violent pain in the knees and abdomen, and sank to the sidewalk. Thence he was conveyed to the hospital.

When I saw him, on the third day, he was still very weak in the lower limbs, but could move them somewhat, but not without pain. These pains could also be induced by backward motion. There was no anæsthesia, but, on the contrary, the lower limbs were exceedingly hyperæsthetic. Bladder symptoms requiring the use of the catheter had been present, but were now giving place to incontinence.

Pains, easily controlled with injections of Magendie's solution, ten minims every four hours. No cerebral symptoms nor motor or sensory disturbances in the upper extremities. There has been considerable constipation, which readily yields to purgatives. Patient discharged on the twelfth day.

Case III.—E. N. C——, Irish laborer; had been employed in the tunnel for several days; he suffered no inconvenience on entering the compressed air other than ringing in the ears. Forty-eight hours ago he was brought to St. Francis Hospital, suffering severely from the characteristic symptoms of the disease.

The salient features in the clinical history of the case are as follows: On leaving the condensed atmosphere, or rather shortly afterward, he noticed a peculiar pain in the region of the deltoid muscle. In a few minutes he began to experience an aching sensation in the joints of the arms and legs, and particularly in the knees and elbows. This aching sensation increased in severity with great rapidity, culminating, at length, in pain of excruciating intensity.

Though the pain in the arms, and more especially that in the shoulders, was very great, it was not so severe as that felt in the lower limbs. In the last-named situation it was referred to as a "tearing pain in the bones." The bladder symptoms were insignificant, and there was at no time impairment of sensation or motion in the legs. The functions of the rectum remained normal.

The treatment adopted was very simple, consisting mainly in the administration of purgatives, and Magendie's solution of morphine, in doses of ten minims, every three or four hours. On the day following admission he ap-

peared very weak, and was quite unable to take other than fluid nourishment, although the abdominal pains were quite insignificant. From this time till the twelfth day the pains, which were gradually diminishing in severity and frequency, were well controlled with morphine; and on the twenty-third day from the date of his admission he had quite recovered, and was able to take his departure from the hospital on foot and unassisted.

Case IV.—N. A——, German workman, of middle age. Presents features almost identical with those of Case III., except that there was at first some anæsthesia of the lower extremities, culminating soon afterward in severe hyperæsthesia, and also pronounced bladder symptoms, requiring the use of the catheter for a few days. There was likewise some paresis of the legs.

Case V.—R. V——, Scandinavian (?) laborer; had worked in the tunnel but three days, when, on emerging the last time, he was seized with a dull pain in the knees, soon followed by violent "cramps" in the abdomen. He then, according to his own statement, lost consciousness, and has no recollection of what followed till he found himself in the hospital. So far as I was able to ascertain, he regained consciousness about twelve or fourteen hours after his arrival at St. Francis. When I saw him, a few days after admission, his lower limbs were paralyzed and anæsthetic. He could not feel the prick of a pin in the thigh or ankle, neither could he distinguish a piece of ice nor a hot towel when placed upon his legs. On the other hand, he was well able to tell when his legs were pressed upon, or when an object of any considerable weight was placed upon them. Both the bladder and the rectum were affected. In the case of the former the detrusor was paralyzed, so that the use of the catheter was made necessary, whereas in the case of the rectum paralysis of the sphincter was the more obvious feature.

The first time I saw him he had just received a dose of morphine, so that he felt but little pain. Nevertheless, after waiting some time at the hospital till the effect of the drug had worn off, the pains again returned, and I was able by careful interrogation to inform myself with great exactness as to their character and location. I found that the man felt pain in his legs, back, arms, and chest; and that while that in the lower extremities was described as "tearing and grinding," that in the arms as "aching," and that in the chest as "crushing," the pain in the back had something *sui generis* about it and was referred to as "burning." Of course, as the man was a foreigner, his descriptive powers were much curtailed; still, his knowledge of English was fair, and I am inclined to think that his declaration as to these manifold pains was substantially correct. There was nothing specially novel in the subsequent course of this case. The deranged functions of the bladder and rectum disappeared in a relatively short time; the anæsthesia, as is usually the case, gave place to hyperæsthesia; and somewhat later the motor functions also gradually returned, the patient beginning by moving his toes and ending by walking about the wards. He was discharged recovered, I believe, at the end of the third week.

Case VI.—American, of Irish parents; had been at work in the tunnel for about a week. On entering for the last time on Saturday, he noticed that the buzzing in his ears was very loud, and that he was more readily fatigued than on former occasions. On leaving the condensed atmosphere he felt very cold, and a few minutes later his knees began to ache. Realizing from what he had heard from other workmen that he was about to be attacked by the disease, he made an attempt to regain the tunnel, hoping to abort the seizure. He did not, however, succeed in reaching the shaft, but fell to the ground in great agony before he had gone half-way. When brought to the hospital he was suffering great agony, the pains being most pronounced in the back, knees, chest, and abdomen. No anæsthesia was present, but, on the contrary, the lower limbs were hyperæsthetic from the beginning. In other respects, also, the symptoms and termination were practically like those of Case II., so that nothing further need be added to the clinical history.

Case VII.—L. K——, robust man in middle life, of German parentage, formerly a soldier in the United States Army; has been at work in the tunnel for the past six weeks. During this time he has been quite well, with the exception of a slight attack of "the bends," assuming the form of stiffness in the legs. This minor attack of the disease came on after he had been at work in the tunnel four days; it was of short duration, and disappeared in the course of twelve hours. In addition to this indisposition he subsequently noticed, it is true, certain symptoms in the arms, which he describes as "shooting" or "darting" pains. As nearly as I could ascertain these pains made their appearance on the fourteenth day, about ten minutes after he had left the tunnel. These, too, soon disappeared, and he felt as well as ever.

The present attack came on during the beginning of the seventh week of his engagement in the tunnel. Briefly stated, he had been out of the condensed atmosphere half an hour or less, when he was seized with excruciating pains in the chest, shoulders, back, and abdomen. There was also at first some pain in the knees, but this was completely dwarfed by the agonizing sensations in the trunk. Coincidently with the advent of the pains, there was complete loss of power in the legs, which caused him to fall heavily to the floor. He was conveyed, like the preceding cases, to St. Francis Hospital, and there, four days after his admission, I had a very excellent opportunity of examining him. His lower limbs were completely paralyzed and sensation was likewise abolished, the zone of anæsthesia extending a hand's-breadth above the crest of the ilium in front, but not so high behind. The genital organs were quite insensitive, as was shown by repeated tests with the sharp points of an æsthesiometer. Both the bladder and rectum were paralyzed and the patient complained of severe vesical tenesmus. Though his water was frequently drawn with the catheter the tenesmus was not relieved.

He is very thirsty and drinks water in small quantities at frequent intervals. He cannot retain solids, and is fed with liquids only. As in the previous cases, the pains are controlled with morphine, and the bowels are kept open with purgatives.

Ten days later I again examined this patient most carefully, and found that his rectum was completely anæsthetic and still paralyzed, defecation taking place unconsciously, and quite independent of any volitional control.

This case remained under treatment for a long time, and when discharged I am told there was still great weakness in the legs, and that the patient's general health was far from satisfactory.

Cases VIII. and IX. occurred in men who had been employed in the tunnel for a short time only. Neither of these cases presents features of special interest. Both experienced the characteristic pains in the knees and abdomen, and in other respects were quite like Case III.

Pathogenesis.—It has already been shown that the attack does not occur as a consequence of a prolonged sojourn in highly condensed air, but as the result of an *abrupt transition* from an atmosphere of high density to one which is relatively rarefied. Nor is it necessary that this transition should take place from an atmosphere which is more condensed than that in which human beings are accustomed to live. As an absolute proof of this proposition I will merely cite the fact that aëronauts who ascend rapidly to great heights are sometimes attacked in the lofty regions above the clouds, where the barometric pressure is relatively low, by symptoms in all essential particulars like those of the caisson disease.

An illustration in point is that of Mr. James Glaisher, the famous aëronaut, who made a series of twenty-eight ascents, most or all of which were undertaken for the purpose of scientific research. The most thrilling of these voyages in the air was that undertaken on September

5, 1862, from Wolverhampton, a town in the centre of England. In speaking of this remarkable ascent Professor W. Le Conte Stevens observes in his recent most instructive paper on aëronautics :[1]

"The intention was to reach the greatest height possible. The balloon left the ground at a few minutes past one o'clock, and at the end of forty-five minutes a height of five miles was reached. Mr. Glaisher began to grow faint on account of the rarefaction of the air. When half a mile more had been mounted, Mr. Glaisher lost the use of his hands and limbs. . . . A few moments afterward he fell back insensible in the car.

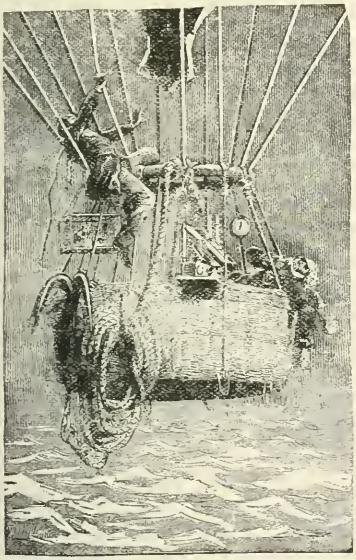

FIG. 6.—Glaisher Insensible at the Height of Seven Miles.

His companion, Mr. Coxwell, who had been employed as aëronaut, here attempted to stop the ascent by pulling the valve-rope; but this had become twisted on account of the rotary motion of the balloon. It was necessary to climb up into the rigging to disentangle it. On attempting to come down he found his hands frozen, and insensibility beginning to creep over him. Placing his arms on the ring, he dropped down into the car. After several ineffectual efforts he succeeded in catching the valve-rope with his teeth, and by dipping the head a few times he caused the escape of enough gas to make the balloon take a decided turn downward. Glaisher soon recovered and resumed his observations upon the instruments."

From the data afforded by the instruments it was shown that the maximum elevation had been 37,000 feet, or seven miles. The ground was at length reached in safety, about one hundred minutes after the departure from Wolverhampton.

Thus ended one of the most thrilling aërial voyages on record.

The analogy between Glaisher's recovery as the balloon descended to a denser atmosphere, and the recovery of one afflicted by the caisson disease on re-entering the caisson is at once apparent. Finally, there can be no doubt that the paresis of the muscles of the hands, feet, and trunk, as well as the somnolency and ultimate unconsciousness which occurred in Mr. Glaisher's case were the *direct result of the diminished atmospheric pressure and not the effect of cold*, since similar phenomena may be induced in animals experimentally by exposing them in suitable apparatus to air of corresponding rarefaction.[1] The physiological *modus operandi* is evidently quite simple : In the first place, the diminution of the pressure at the periphery causes the blood to rush in unwonted quantity to the surface of the body, with consequent deprivation of the internal organs, and especially those within the cerebro-spinal canal, of a large amount of blood.

This anæmia of the cord and brain is equivalent to a withdrawal of a large amount of oxygen from those structures, to the serious impairment of their functions. As a matter of necessity this anæmia will first make itself felt in the lower segments of the cord, for the very good reason, as Dr. Moxon[2] long since pointed out, that the arteries which supply this region are at once long, slender, and remote from the heart. Only when the rarefaction is very great will the cerebral functions be affected. Hence there will be motor and sensory paraplegia before unconsciousness.

That such circulatory derangements should produce something more than transient effects is not to be wondered at; at least we need not wonder that damage is wrought, *if the subject remain in the relatively rarefied air*, as he does if he fails to descend from a very great height (in a balloon) or if he fail to re-enter the caisson after the characteristic pains have set in. How disastrous may be the effects of a prolonged anæmia upon nervous structures special pathology has abundantly shown. When we consider how great and how prolonged is the derivative action consequent upon the transition from a condensed atmosphere to one relatively rarefied, and when we bear in mind how feeble is the heart's action for a long time after such transition, it is in no sense special pleading when we look to the local anæmia and consequent defective oxygenation of the cerebro-spinal axis, and particularly of its lower segments, as the true cause of the characteristic symptoms of the caisson disease.

Dr. Andrew H. Smith has given a somewhat different interpretation of the phenomena of the caisson disease. He believes that the capillaries of the brain and cord are inordinately relaxed (stretched) by the condensed air, and that they do not at once resume their tone after the subject has left the caisson. Hence "the capillaries being clogged with effete blood, the nutrition of the part must suffer, and disturbances of function will result."[3]

But Dr. Smith's theory is so ingenious, and reinforced with such cogent reasoning withal, that I cannot forbear presenting it more fully in his own language.

As a preface to his argument he lays down three propositions : First, "That under high atmospheric pressure the centres will be congested at the expense of the periphery; secondly, that firm and compact structures will be congested at the expense of those more compressible; and thirdly, that structures within closed bony cavities are congested at the expense of all others."[4]

"In accordance with these laws we shall find that while in the caisson the condition of the different parts in regard to the supply of blood will be as follows :

"The skin and the superficial structures will be anæmic. (This is shown by the pallor, which is very characteristic.) The central portion of the limbs and the interior organs of the body will be congested. The solid viscera of the abdomen will be especially engorged on account of both situation and structure. The brain and spinal cord and the interior of the shaft of the long bones will be congested to a high degree from the operation of the third law.

"These changes are not perfected until a considerable time has been passed in the compressed air. The circulation up to this point goes on everywhere with vigor, the

[1] The Scientific American Supplement, February 22, 1890, p. 11792. The accompanying engraving is taken from Professor Stevens' paper. The plate was kindly loaned me by the editor of The Scientific American.

[3] The Effects of High Atmospheric Pressure, including the Caisson Disease. By Andrew H. Smith, M.D., etc. Brooklyn. 1873.

[4] Op. cit., p. 31 et seq.

change being in the relative calibre of the vessels, not in their tension. The counter-pressure becomes uniform throughout the whole vascular system, but this counter pressure suspends the natural muscular resistance or tone of the vessels, which have become passive tubes. The blood is distributed not in accordance with the physiological demands of the different parts, but in obedience to overpowering physical force.

"This is the condition of the circulation at the moment that the process of locking-out begins. Yet the changes which have taken place up to this point are not the cause of the morbid phenomena which constitute the caisson disease, else the attack would take place while in the compressed air instead of after leaving it. It is evident that the removal of the pressure, and not the pressure itself, is the immediate cause of the seizure.

"This removal is effected in the few minutes which are occupied in locking-out. But it is not to be supposed that the vessels will instantly assume their normal condition. They are in a state of relaxation, not only in the congested but also in the anæmic parts; in the former because of over-distention, in the latter because the muscular coat cannot at once recover from its inaction. The aggregate capacity of the vascular system will, therefore, be in excess, compared to the volume of blood to be conveyed; or, in other words there will be a lowering of vascular tension.

"Hence, the circulation will be languid, and the congested parts will not readily empty themselves of the excess of blood which they contain. Especially will this be the case in the brain and spinal cord, where the conditions are most favorable for the production of congestion. The capillaries being clogged with effete blood, the nutrition of the part must suffer, and disturbances of function will result.

"It is to this, I think, that the delirium and the transient loss of consciousness, which occasionally occur, are to be attributed. When the spinal cord is the seat of this condition, pain in the parts deriving their nerves from that section of the cord may result, or paralysis more or less complete may follow." [1]

Morbid Anatomy.—The pathology of the caisson disease is not in a very satisfactory condition. This is not difficult to account for when we consider that only the severest cases come to autopsy, and that the congestion described in such cases may be secondary to a condition of partial softening, which, in turn, may be due to a primary anæmia, which, however, no longer exists.

Leyden and F. Schultze were, according to Strümpell,[2] the first to conduct special anatomical investigations in such cases. They found "a disseminated but extensive affection of the dorsal cord, chiefly in the posterior columns and the posterior portions of the lateral columns. The nervous tissue in the diseased parts was completely destroyed, and instead of it was found detritus and a collection of large, round, finely granular cells (fatty granular cells?)."

At one time it was believed that, on leaving the condensed atmosphere, there was a development of gas from the blood which caused a rupture of the neighboring tissue. What added plausibility to this theory was the fact that Bert and Hoppe-Seyler had been able to produce analogous phenomena experimentally.

It has been urged, however, in rebuttal, that the limitation to the dorsal portion of the cord and the infrequency or total absence of vascular hemorrhage are totally opposed to this theory.

It is evident from the foregoing that not much can be learned regarding the primary vascular condition, which lies at the root of subsequent pathological events, from mere patho-anatomical considerations.

Treatment.—The treatment adopted in those cases which occurred in the Hudson River Tunnel, and which were brought to St. Francis Hospital, was quite simple. Morphine was given at frequent intervals (every two or three hours) to control the pains; the bowels were relieved with cathartics, for derivative purposes; the catheter was used when the retention was such as to require it, and the patient placed upon a fluid and nourishing diet. In some cases ergot was also given with apparent benefit; and I may add, also, that the faradic battery was sometimes applied to the seat of pain at the tunnel. Contrary to the expressed opinions of some writers, I am firmly impressed with the fact that these applications of the electric current did good; for I have repeatedly had patients tell me that the pains were greatly relieved by them.

Dr. Jaminet has a high regard for stimulants, which he gives in conjunction with concentrated nourishment, ignoring anodynes altogether. Dr. Smith, on the other hand, is of the opinion that the prime indication is the alleviation of the severe pains which are so distressing a feature of the affection. I am entirely in agreement with him on this point. To this end he gives large doses of morphine (from one-fourth to one-half grain).

With a view to causing contraction of the distended capillaries of the brain and cord, the same observer was led to test the efficacy of ergot. This mode of treatment, though not always successful, was, in his opinion, sometimes productive of the happiest results. In some instances the pain was relieved in half an hour after the administration of a drachm of the fluid extract. The injection of ergotine, hypodermically, did not, however, yield equally good results, as considerable irritation was set up at the point of insertion.

Compression of the arteries and veins of the lower extremities has been tried, with a view to arresting pain in the knee, but the results obtained were not satisfactory. Cold applications and douches to the spine proved beneficial in two of Dr. Smith's cases. Jaminet found that hot baths were followed by serious accidents, so that he was led to interdict their employment. Chief among the disagreeable consequences observed was paralysis, which sometimes came on while the patient was still in the hot bath.

No marked benefit was derived by this observer from the use of electricity. Dry cups to the spine seem to have given good results in some cases.

Unquestionably the best of all remedies is to return the patient as quickly as possible to the condensed atmosphere. All physicians who have had occasion to study the disease agree that if the subject can be brought into the caisson again upon the outbreak of the characteristic symptoms, the latter speedily disappear. As Dr. Smith observes, however, such a course is not always possible, owing to the feeble condition of the patient on the one hand, and the inaccessibility of the caisson on the other. The foregoing objections have induced him to propose the following plan for employing compressed air at some point above ground which would be easily accessible: "Let there be constructed, of iron of sufficient thickness, a tube nine feet long and three and one-half feet in diameter, having one end permanently closed, and the other provided with a door opening inward, and closing air-tight, this tube to be placed horizontally and provided with ways upon which a bed could be slid into it. Very strong plates of glass set in the door and in the opposite end would admit the light of candles or gas-jets placed immediately outside. This apparatus should be connected by means of a suitable tube with the pipe which conveys the air from the condensers to the caisson. An escape-cock, properly regulated, would allow the constant escape of sufficient air to preserve the necessary purity of the atmosphere within.

"The bed containing the patient having been slid into the chamber, the door is to be closed and the pressure admitted gradually until it nearly or quite equals that in the caisson. This should be continued until the patient indicates by a signal, previously concerted, that the pain is

[1] Op. cit., p. 32.

[2] A Text-Book of Medicine, p. 575. By Adolf Strümpell. (American edition.) New York: D. Appleton & Co. 1887.

relieved. The pressure should then be reduced by degrees, carefully adjusted to the effect produced, until at last the normal standard is reached. By occupying several hours, if necessary, in the reduction of the pressure, it is probable that a return of the pain could be avoided.

"The apparatus once provided there would be no difficulty in carrying out the plan in any case of such severity as to resist other treatment. I should expect the very best results from it in cases of extreme pain, or in the very outset of paralysis not dependent upon extravasation of blood.

"Of course the secondary conditions which arise in protracted cases would not be capable of direct relief by simply reproducing the physical conditions existing in the caisson. The most that might be hoped for in such cases would be that the pressure might result in giving a new impulse to the circulation in the congested part, and thus favor resolution."

Prophylaxis.—Only men of strong constitutions should be allowed to engage in submarine work necessitating the employment of condensed air. The food should be of the most nourishing description, but alcohol, on account of its relaxing effects upon the vaso-motor apparatus should be withheld. It is clear, from the observations of those who have had opportunities for studying the disease, that the duration of the sojourn in the caisson has much to do with the development of the symptons. Short shifts are therefore to be recommended.

Finally, both engineers and physicians agree that a longer time should be consumed in the process of "lock ing out," so that the transition from the condensed to the normal atmosphere may be as gradual as possible.

A Pauper City.—That is what the Philadelphia *Times and Register* calls that city, because 214,000 of its inhabitants received free medical attendance at the various public hospitals and dispensaries during the past year. Our esteemed contemporary says that there is entirely too much beneficiary work done in Philadelphia, and innocently asks whether this state of affairs is as bad in other great cities. Indeed it is.

NEURASTHENIA AND NEURALGIA FROM TRAUMATISM OF THE NASAL PASSAGES.

By W. F. CHAPPEL, M.D., M.R.C.S. Eng.,

NEW YORK.

The past three years has seen a marked increase in our exact knowledge and appreciation of the condition of persons said to be neurasthenic. When Beard classified the symptoms of this disease and gave them a name, many physicians, especially in Europe, did not believe it to be a definite disease, traceable to certain causes, giving a definite train of symptoms, and requiring most skilful treatment. They had been accustomed to say that these sufferers were overworked, hypochondriacal, or a little hipped. The latter word was used in England to specially describe the condition we now know to be one of neurasthenia.

Neurasthenia has been mostly confined to the practice of physicians. Some recognize three classes of this affection: 1. Reflex. 2. Lithæmic. 3. Simple neurasthenia.

The latter the most frequent, and due to overwork and excesses of various kinds. During the past eighteen months, much fruitful observation and investigation has been pursued in this field by neurologists and surgeons. They have frequently warned the profession of the serious nervous disturbance which occasionally follows operations and accidents accompanied by severe shock. This condition is now so well recognized as to be called traumatic neurasthenia and traumatic neurosis.

This form of neurasthenia has been studied and described as occurring chiefly after railway and other serious accidents. There is nothing specific, however, in these accidents, to produce this peculiar and definite train of symptoms. They may be caused by anything which produces great shock or fright, especially in certain persons whose condition is favorable for their development. We all know that the influence of a neurosis may never manifest itself, unless overwork, accident, or fright determines its appearance.

Oppenheim, quoted by Dr. Henry Hun, says, the principal symptoms of this condition are mental depression, hallucinatory delirium, vertigo, and spasms. There is a combination of hyperæsthesia and anæsthesia not only of the cutaneous nerves, but also of the special senses; tremor is common, palpitation frequent, and also a failure of the general nutrition.

Hun, again quoting from Strümpell, says, that the latter divides these cases into those suffering from general traumatic neuroses, and a second class from local traumatic neuroses. To the first class belong those cases which after a severe shock or concussion develop certain well-defined symptoms referable to the nervous system, and similar in every way to what is known as neurasthenia, melancholia, etc.

To the second class belong those severe nervous symptoms, such as local paralysis, contracture, hyperæsthesia, seen occasionally after severe local injuries, and due entirely to psychical excitement associated with the injury of the part.

Knapp, Shaw, Seguin, and several other writers have given this subject attention during the past year, but I have quoted enough to show you how important this class of nervous symptoms is considered.

In my opinion, operations in the nasal passages offer a most favorable opportunity for the development of traumatic neuroses—their mucous membrane has an abundant nerve distribution in intimate relation with the most important nerve-centres; we cannot easily reduce or prevent shock in these operations by the use of ether and chloroform, as the necessary position and co-operation of the patient prevent their use. Cocaine, if used freely, will relieve the pain in most cases, but there are some in which no amount of cocaine seems to render anæsthesia complete. Even when we do get immunity from pain, the patient is able to feel the grating of the saw or the pulling and pinching of the forceps and wire. To those who are not familiar with these complaints, this may seem a matter of little importance, but be assured anyone who has had personal experience, or seen the effect on some of the patients, will readily realize that fear is more distressing than pain, and that a serious nervous disturbance might be produced in some persons.

I shall now relate short histories of six cases of nervous disturbance following operations in the nasal cavity.

O. H. R——, aged thirty-six, clergyman; had never had any serious illness; while not a decidedly nervous person, always consulted his physician about slight ailments, and was very anxious until he had entirely recovered. For five years had suffered from post-nasal discharge, due to hypertrophic rhinitis and a large bony spur growing from the anterior part of the septum near the floor of the left naris. I injected monochloracetic acid into the hypertrophied mucous membrane three times in 1889, averaging three months apart. This relieved the post-nasal discharge very much. On January 9, 1889, he consulted me again, as he still had some discomfort from post-nasal mucus. I then removed the spur with a saw, using cocaine freely. There was little hemorrhage and no pain, but loud complaints about the grating of the saw. A small ledge of the spur remaining on the lower part of the cut surface, I removed it with Dr. A. H. Smith's cannula scissors. The patient immediately complained of intense pain and burning sensation in the centre of the forehead, which continued for several hours. In the afternoon of the same day, on attempting to write, he found he was unable to compose with clearness and readiness, and with great difficulty finished a disconnected letter. In the evening he took up the newspaper, but was unable to read, as he could not connect the sentences and their meaning. He remained in the city for a few days, still feeling very weak and nervous. He constantly said he felt that he would never be able to resume his duties.

January 13th, while delivering a sermon, he found great difficulty in choosing words to express himself, and with great effort concluded his discourse. The same day he forgot to pronounce the benediction, and when reminded of his neglect, could not recollect the omission. The following week he was very depressed and totally unable to do anything. He wished to sit quiet and not be disturbed. The next Sunday he had what he called his nervous chills and violent palpitation of the heart, produced, he thought, by a dread that he would break down during his morning service, or make some blunder without being aware of it.

January 28th, he called to see me, and after relating the foregoing symptoms, added that he had a tight feeling around the head, pain in the occipital region, and a general feeling of confusion. He was perfectly hopeless about the future and said he would never preach again, and that he was going to resign his parish. On examination, I found the wound healed, and with no particularly sensitive spots. His physical condition was good; pulse, 90; temperature normal; urine pale straw in color; specific gravity, 1.018, reaction faintly acid, no albumin or sugar. At the suggestion of Dr. A. H. Smith, I applied Paquelin's thermo-cautery lightly to the back of the patient's neck and spine every other day for a week. He then returned home, somewhat improved. October 10th, visited me again and reported that he had been very miserable and despondent for months past. During the summer had six weeks holiday, but was very little improved by it. Crowds and noises made him nervous and chilly. The ringing of bells brought on a violent attack of palpitation. At this date (October 10th) he seemed quite as ill as in January. Complains constantly of the tight feeling around the head and hot sensation in the frontal region, occasional pains behind the ears and in the back of neck. Says he has a numb feeling behind the left ear and a belief that the brain in that region don't act. Still has difficulty in originating new ideas, and also in reading and writing; has none of his old enthusiasm in

his delivery or work; when reading aloud had difficulty in forming his lips to pronounce the words. A month later his condition was unimproved and he consulted Dr. C. L. Dana, who made the diagnosis of traumatic neurasthenia and advised prolonged rest.

I saw this patient on the 8th of the present month, just one year and three months since the operation; he was unable to take the complete rest advised, and continued his duties; he did everything to improve his general condition, and says his improvement was gradual. He is now in very robust health, in fact has never been so well; has none of the head symptoms he had six months ago, but if very tired, has a stiff feeling in the frontal region.

J. G——, aged twenty-six, came to the out-door clinic of the Presbyterian Hospital in October, 1888. He had always been in good health, but was of a nervous temperament and very anxious about his present condition. For two years had been unable to breathe through his left nostril, owing to a large spur growing from the lower part and centre of the septum. I removed this at once with the saw. He complained greatly of the sawing sensation, and said he felt it at the top of his head and his teeth. Two hours later, he had a tight feeling around the head and numbness of left arm, and, as he described it, creeping feelings down his back. The following day he was despondent and easily moved to tears. Said he could not think; reading had no interest for him; he felt he would never be able to work again. Three weeks later, the numbness left the arm. The other symptoms improved gradually, but he was not well until six months later.

Mrs. W——, aged sixty-eight, suffered occasionally from headaches, otherwise enjoyed good health. The mucous membrane covering the middle turbinated bodies was much hypertrophied and hung in pendulous masses, occluding the nares. After using cocaine, one drop of monochloracetic acid was injected into the mucous membrane of the right side. There was a little pain, which ceased before she left the office. In the evening severe pain attacked the right side of the face, extended from the right frontal sinus over the top of the head to the occiput, and a slight aching down the back. The pain also extended down the right side of the neck, and along the course of the large nerves to the tips of the fingers. The intensity of the pain increased toward evening, and on change of temperature or position. The suffering was intense, due not alone to the neuralgic pains, but also to a tender condition of the integument and cellular tissue of the affected part.

The pain subsided after the first week, but six weeks elapsed before the patient was at all comfortable. During the attack and for months after, she was much depressed and her physical condition greatly enfeebled. She has quite recovered her strength now, but on exposure still has pain and tenderness of the face. I might add that the injection of the acid gave permanent relief from the hypertrophied mucous membrane.

E. F——, aged forty-four. January 17, 1890, I removed a portion of the hypertrophied left middle turbinated body; on February 3d, I attempted to remove another portion of the same middle turbinated; while doing so, I felt what I feared was the separation of the whole bone from its attachment. I desisted at once. A good deal of hemorrhage followed, but little pain. The following day, the patient reported that about two hours after the operation, she began to suffer from pain and tenderness over the left frontal region, extending to the occiput and down the back of the neck to the left shoulder. She felt dizzy and feared at times she would fall. It is now three months since the operation, and although much better, still has some numbness of that side of the face and neck.

The next two cases occurred under the care of Dr. James E. Nichols, to whom I am indebted for permission to report them.

S. I——, aged twenty-five. In October, 1889, Dr. Nichols removed a spur from the right side of the septum. The patient seemed greatly impressed by the operation. Although the pain and hemorrhage were slight, he fainted. The following morning he complained of a dull aching in the occipital region, which extended down the spine and was specially severe in the dorsal region. There was also considerable pain under the right eye and a feeling of constriction around the head. He was much depressed, felt weak and disinclined to work. These symptoms were pronounced and severe for three weeks, when he began to improve, but is not well yet, as he still has occasional aching in the cervical region and also the occiput, a nervous, restless feeling, and considerable insomnia.

Mrs. E. F. W——, aged forty-four. Came under Dr. Nichols' care in September, 1888. She had always been considered to be of a nervous temperament. Eight years ago, she had an operation for lacerated cervix. After the operation she said she suffered many weeks from nervous prostration. Three years ago she had a mild attack of sunstroke. When seen by Dr. Nichols, she had a troublesome cough, which he thought was due to congestion of the pharynx. After remaining under his care for three weeks, she returned home much benefited. In October, 1889, she again visited Dr. Nichols, as the cough still continued. On October 19th he removed a portion of the left middle turbinated body with Weir's forceps, and used the galvano-cautery on the inferior turbinated of the same side. The pain was not severe, but the patient vomited and complained of tenderness and pain in the back of the neck. October 28th, the galvano-cautery and chromic acid were used to the right inferior and middle turbinated bodies. Soon after the application she had pains in the head and an aching of the neck and shoulders. For several days she felt sore all over, the knees being particularly lame and tender. When she seemed quite well again, the doctor removed some mucous membrane from the left middle turbinated body with the cold wire snare. He also applied chromic acid to the posterior extremities of the inferior and middle turbinated of the right side. The application of the chromic acid was followed by intense pain in the back of the neck, throat, top of the head, elbows, wrists, knees, and ankles—in fact, as Dr. Nichols said, it seemed a "storm of pain." This condition continued for several hours, when she was removed to her apartments and put to bed. Remedies were used to relieve the pain and produce sleep, but they had little effect. The following day she had great pain over the bridge of the nose, vertex, back of the neck, anterior border of the sterno-mastoid muscles, and extending to the tips of the fingers. She was unable to move any part of the body without severe pain and tenderness, and suffered also from partial aphasia, which became complete at times.

On the third day after the operation, she fell into a cataleptic state from which she could be aroused with difficulty—pupils contracted, respiration shallow, heart's action normal. This cataleptic condition continued over an hour and recurred daily for the succeeding ten days. General hyperæsthesia was very marked. Exposure to the air or the slightest touch caused great pain. These symptoms continued with little improvement for the next two weeks, when a tender red swelling appeared on the left instep, and also one in the palm of the left hand. These spots puffed up at times and became extremely sensitive.

On November 23d (over a month after the operation), she had improved sufficiently to allow of her removal to Mount Vernon, N. Y. The change seemed beneficial, and a month later she was removed to her home in Vermont. At the present time, she is far from being in her usual health. The swelling on instep and palm of hand are now quite hard and tender when pressed. This case was seen by several physicians in consultation with Dr. Nichols, and pronounced peripheral neuritis.

These cases represent three classes of affections fol

lowing operations, viz., neurasthenia, neuralgia, and peripheral neuritis. My first two cases, and one of Dr. Nichols, showed marked symptoms of neurasthenia immediately following the operations. While these patients would be considered as belonging to the neurotic type, none had previously shown any of the symptoms they now developed, nor had they any reason for posing as invalids or objects of sympathy. I was very careful not to make any suggestions or ask any leading question about the feelings of these patients, but allowed them to describe their symptoms in their own words. I mention this, as Dr. Seguin, in writing of traumatic neuroses, says that suggestions or leading questions planted in such a psychic soil are pretty sure to bear fruit; they germinate and expand later in the form of new and "interesting" symptoms, the reality of which the patient never doubts. The neurasthenic cases bear a marked similarity in their histories. The sudden development of the symptoms immediately after the operation, all complained of pains and peculiar feelings in the frontal region and between the eyes, constriction around the head, and pain in the occiput, inability to read or sustain thought, great depression of spirits, and hopelessness about the future. They are quite unable to perform their ordinary duties and employment, and feel they will never be able to do so, and are constantly fearing some new affliction.

The prognosis of traumatic neuroses following railway and other serious accidents, is said to be very unfavorable; but judging from these cases, recovery seems certain, although prolonged. It seems to depend somewhat on the severity of the shock and the condition of the patient at the time of the operation. The cases of Mrs. W. and Mrs. F. were more neuralgic in their character; while both suffered from depression and other neurasthenic symptoms, it was probably due to the extreme pain they experienced.

I might relate many cases of pain in the teeth, eye, ear, face, and head attending operations on the nasal passages, but it would only be making statements with which many of you are already familiar.

In conclusion, gentlemen, I think you will bear me out in the statement that operations in the nasal passages should not be undertaken lightly, and with the impression that, if they don't do any good, they will not be harmful; also that great experience and judgment may be required to determine the cases suitable for operation and likely to be benefited thereby.

The cases I have given you to-night bring before us another condition which must always be taken into consideration, and from my present experience I would advise a careful inquiry into the past history of every case before operation, and a careful examination of the present state of the nervous system. If the patient is very neurotic or gives a history of having suffered from what is called nervous prostration, although the physical condition might be excellent, I would discourage operative measures, unless imperatively demanded.[1]

A Grasping Lot.—The story is told in the newspapers that a certain M. Heriot, the owner of the big store called the Louvre, in Paris, was sent to the insane asylum by his relations because he insisted upon giving $1,000,000, which he could readily afford to lose, to founding an orphanage for soldiers' children. The local authorities finally ordered that he should be removed from a private asylum and placed in a public one, and it was quickly found that he was not insane at all. For thirteen months' treatment the private asylum doctors demand $22,500, the local doctors want $20,000, three medical students who helped find him crazy, $13,500, and the keepers $5,000.

[1] I relate the following incident, as an amusing illustration of the effect of impressions on some persons: One of the lady type-writers who made copies of this article, while reading the description of the grating of the saw in the patient's nose, became hysterical and, as she expressed it, nervously prostrated at the idea, and was unable to work for the remainder of the day.

DR. FREIRE'S PROTECTIVE INOCULATION —FACTS VERSUS FIGURES.

By GEORGE M. STERNBERG, M.D.,
MAJOR AND SURGEON, U.S.A.

THE MEDICAL RECORD published some time since a translation of a communication, made by Dr. Domingos Freire, of Brazil, to the French Academy of Sciences, relating to his protective inoculations. This summary statement has been copied in this country by *Science*, and probably by other journals, and will doubtless be read by many who will never see a copy of the volume containing my official report[1] of investigations made in Brazil, in which I show that Dr. Freire's statistics are misleading, and that his "vaccinations" have no prophylactic value.

Dr. Freire's recent statistics have also been brought to the notice of the profession by an article by Dr. J. McF. Gaston, published in the *Journal of the American Medical Association*, March 22, 1890. In order that the profession in this country may be able to estimate Dr. Freire's statistics at their true value, I beg leave to call attention to the following facts:

First, there has been no veritable discovery of the specific germ of yellow fever, and consequently there is no "attenuated virus" at Dr. Freire's command with which to vaccinate against the disease. It is certain that the micrococcus, which he presented to me at the time of my visit to Brazil as his yellow fever microbe, has nothing to do with the etiology of this disease. A careful bacteriological study of forty fatal cases, made in Havana since my return from Brazil, enables me to affirm this in the most positive manner.

There is then no scientific basis for the wholesale inoculations which Dr. Freire has made, and his statistics, when viewed in the light of certain facts not brought out in his publications, give no substantial support to his claims.

As my personal investigations were made in the city of Rio de Janeiro, and a majority of Dr. Freire's inoculations have been made in that city, I shall consider at present only those figures which relate to his recent inoculations in the Brazilian capital. With reference to these, Dr. Freire says in his latest publication:[2]

"Between March 1 and June 30, 1889, 2,407 persons died of yellow fever (including the deaths at the Jurajuba Hospital), 21 of whom had been vaccinated—that is to say, that 2,386 non-vaccinated persons succumbed to the disease (1,606 in the city, 800 at Jurajuba, in all)."

Now, the total population of Rio is estimated at 400,000. Let us suppose that 100,000 of this population enjoys protection from having suffered an attack of the disease; we have left 300,000 persons who may fairly be compared with those vaccinated by Freire, and who were exposed during the epidemic. The mortality upon this estimate is 1 in 125 and a fraction ($\frac{300000}{2386} = 125.7$). Among the 2,087 vaccinated there were, according to Dr. Freire, 21 deaths (loc. cit., p. 16), that is, 1 in 99 and a fraction ($\frac{2087}{21} = 99.38$). It will be seen that this comparison is not at all favorable to Dr. Freire's method. But no doubt he will claim that the comparison is unfair, and that the 2,087 vaccinated by him represent a greater proportion of susceptible persons than the 300,000 with whom we have compared them. Let us, then, deduct another 100,000 of the population, considering one-half as protected by a previous attack or long residence in the city. The remaining moiety includes the entire foreign population, Brazilians not born in the city of Rio, all young children, who, according to Freire, are to be classed with strangers as to susceptibility; in short, a population that may be fairly compared with those vaccinated.

The ratio of mortality under this estimate is 1 in 83 and a fraction ($\frac{200000}{2386} = 83.78$). But in this compari

[1] Annual volume of the Marine Hospital Service for 1889.

[2] Statistique des vaccinations au moyen des cultures du microbe attenue de la fièvre jaune (Rio de Janeiro, 1890).

son we have ignored some very important factors which are in favor of Dr. Freire's statistics. A large number of the deaths, no doubt, occurred among strangers who did not belong to the population of the city, and especially among the sailors on foreign vessels arriving during the epidemic, who are commonly sent to the Jurajuba Hospital when taken sick. On the other hand, we have no definite information as to the precise date when the vaccinations were practised, and no data with reference to the exposure before and after vaccination. In the statistics of previous years a very considerable number of persons were vaccinated after the epidemic had terminated—that is, persons who had passed through the epidemic season without contracting the disease were vaccinated, and counted among those supposed to be protected from an attack by this procedure. Evidently, the later in the epidemic the vaccinations were practised, the less value can be accorded to the subsequent exposure as a test of protection. Previous exposure without being taken sick is, on the contrary, evidence of comparative insusceptibility. To put those vaccinated on the same footing with the 200,000 of the population of Rio with whom we have compared them, they should have been vaccinated at the outset and exposed in the infected city throughout the epidemic season. How many were vaccinated when the epidemic had commenced to decline, or after it had practically terminated? How many left the city soon after being vaccinated? These are questions we cannot answer for 1889, but the facts with reference to 1884, 1885, and 1886 are given in my published report heretofore referred to, some extracts from which I beg leave to quote. Referring to the year 1885, I say:

"Dr. Freire has omitted to state one very important fact with reference to vaccinations practised during the period included in this tabular statement. The date of vaccinations is not given. Fortunately, I am able to supply this omission from his journal containing the names of the vaccinated, which he kindly placed in my hands during my stay in Rio. I find from this record that the inoculations were practised as follows:

January	392
February	342
March	611
April	139
May	273
June	813
July	481

"Now, it is well known that June and July are months during which yellow fever does not prevail in Rio, and that, in fact, the month of May furnishes as a rule but few cases.

"The exposure even in an epidemic year amounts to very little during the months of May, June, and July, and may be considered practically *nil* in a year like 1885, when the whole mortality was only 278 in a city of 400,000 inhabitants. But Dr. Freire has included in his list 1,294 persons who were vaccinated during the healthy winter months of June and July, and who presumably had been exposed during the preceding comparatively unhealthy months of January, February, March, and April. If these 1,294 individuals were protected from an attack of yellow fever by the inoculation practised in June or July, what protected them from being attacked during the preceding epidemic season? We must insist upon excluding these 1,294 persons from consideration during the year 1885, to which the report under review relates, and we think that it would be quite proper also to exclude those inoculated during the month of May, but will not insist upon this point. We have then to consider the value of the evidence offered by Dr. Freire as regards 1,757 inoculated persons, instead of 3,051 included by him in his statistics for the year.

. . . . . .

"Again I find that, in 1886, as in 1885, Dr. Freire has included in his statistics a large number of persons who were vaccinated after the termination of the epidemic, and whose exposure was but little greater than that of the 1,476 imaginary persons who must be added to his list in order to give the mortality of 1 per 1,000.

"Dr. Freire has not given us the date of his vaccinations in his elaborate presentation of his statistical results, but I find from his manuscript record that they were distributed throughout the year as follows—I place in parallel column the figures showing the total mortality from yellow fever during the period:

Month.	Vaccinations.	Total deaths from yellow fever.
1886.		
January	84	135
February	376	234
March	253	347
April	167	220
May	945	48
June	21	18
July	57	9
August	3	2

"This table shows that during the epidemic period, from January 1st to April 30th, there were 880 vaccinations, and during the same period 936 deaths occurred from yellow fever, while during the months of May, June, July, and August, when the total mortality was but 77, the number of vaccinations was 1,026; *i.e.*, a majority of the vaccinations were practised after the epidemic season was over, and upon persons who, no doubt, had for the most part passed through the epidemic season without contracting the disease.

"We turn now to the age of the vaccinated persons. Dr. Freire says, in his report first quoted: 'The greater proportion of the deaths is comprised between one and thirty years. This is, then, the period most favorable for the development of yellow fever. Now, it will be seen that among the number vaccinated, which we give in the second part of our statistics, 2,624 individuals are comprised in this period. But Dr. Freire has elsewhere shown us that the age which gives the greatest mortality is from twenty-one to thirty years. Let us then see what proportion of the vaccinated are included in these limits. Reference to his tables shows the deaths between twenty-one and thirty years of age to have constituted thirty-nine per cent. of the entire mortality, while only fifteen per cent. of the vaccinated fell within these limits of age. On the other hand, forty-three per cent. of the vaccinated were less than ten years of age, while the mortality for this period was only 12.5 per cent. of the entire mortality. We note, also, that a large number of the children vaccinated were infants below two years of age.

. . . . . .

"In Dr. Freire's report under review, he says, on page 7: We include in these figures all the vaccinated during the two previous years *who have been carefully observed during the epidemic season.*

"That portion of the sentence which I have italicized surprises me exceedingly. From what has been said, it will be seen that a careful observation of the floating population of the cortiços, in which most of the vaccinated persons resided, would be practically impossible, even with a large force of inspectors at command.

"Dr. Freire himself did not find time to make the vaccinations among these poor people of the cortiços, but delegated this work to certain apothecaries. One of these, Mr. Telles, informed me that he had himself vaccinated between three and four thousand persons. He also communicated the startling information that none of those inoculated with the 'attenuated microbe' of yellow fever had contracted small-pox during the recent epidemic in Rio, leaving me to infer that the vaccine was a protection against both diseases. This intelligent (?) apothecary, a mulatto, recorded a large portion of the statistics which Dr. Freire has tabulated."

I have said enough to show Dr. Freire's method of manufacturing statistics, and must refer the reader who desires fuller details to my published report.

MANIA AND MULTIPLE NEURITIS IN PREGNANCY.[1]

By WILLIAM M. POLK, M.D.,

NEW YORK.

THREE years ago a patient secured my services in her then impending first confinement, under the following circumstances:

She was twenty six years of age, and had been married a year. Her marriage having been entered into contrary to the suggestion of her physician, whose opposition had been based upon what he believed to be an organic stenosis at the mitral valve. She had become in a measure acquainted with the dangers of pregnancy and labor in the face of such a lesion, and was, therefore, somewhat solicitous as to the outcome of her then condition. Examination revealed a loud mitral stenosis murmur, but apart from that sound the condition of the patient, in all particulars, was as good as could be wished for. This continued to be her state up to the time of labor.

The labor was in every way natural, the supposed cardiac lesion causing no symptoms or inconvenience whatever. She passed through her convalescence remarkably well, and after nursing the child for a short period continued in the best of health. I was surprised at the freedom from all cardiac symptoms, not only because of the very evident auscultatory cardiac indications of mitral stenosis, to my ear, but because of my certainty of the impression which had been made upon her former physician, an eminent specialist in cardiac disorders, and one in whose ability I had implicit confidence. Robust health characterized the case until her second pregnancy, which began in June, 1889. About that time the patient began to be subjected to great mental strain. I saw her in July, and found that the nausea and vomiting of pregnancy were beginning to be very troublesome. I was somewhat surprised at this, because, during the whole of the first pregnancy no such symptom had been present. This disturbance of the stomach became so much aggravated that from July 1st to August 20th very little food could be either taken, or, when taken, retained. A careful examination of the various organs, and of the uterus and its surroundings, failed to reveal a single abnormality.

Under these circumstances, and especially in view of the marked emaciation which had taken place—for she had always been a well-nourished person—the question of the induction of abortion came under consideration. It is as well to say that prior to the consideration of this question all the established agents for the control of such nausea and vomiting had been tried. About August 20th, however, the nausea and vomiting began to grow less, and soon ceased, so that by September 1st an ample supply of food was taken.

With the subsidence of the stomachic symptoms, however, there began to appear evidences of mild mental derangement. Perhaps as early as August 12th the first indications of this condition appeared. By September 20th they were so clearly defined that no one could longer doubt the full development of a mild mania. Coincident with the development of the mental disease there appeared evidence of paralysis of the extensors, first of the upper extremities and then of the lower. The paralysis gradually extended until pretty much all motion of the lower extremities was annulled. The same statement applied to the state of the upper extremities, from the elbow-joint down; the arms could be thrown about, but this seemed to be due mainly to the action of the trunk muscles.

The respiratory muscles next showed signs of paresis, and this also gradually increased until the patient died. This occurred about October 25th. September 20th incontinence of urine appeared. Thinking that it might be due to retention the catheter was used several times, but the bladder was always found empty.

Up to October 1st the temperature had shown occasional elevations, but without regularity; but after October 1st the elevations became more decided and regular, the average morning temperature was 99½°, the afternoon and evening 101°F. Still there was not such regularity as to convince one of the presence of any such poison as malaria or typhoid as a complication. The urine, which had become scanty, now began to show pus, and showed it in such quantities as to convince us that the bladder was the source of the elevated temperature.

From September 10th to the time of the patient's death she took food enough to meet every requirement of nutrition, and during the last three weeks of her life she took even more.

This was associated with alcoholic stimulants in sufficient amount. But notwithstanding the fact that an abundance of food and stimulants were taken and (so far as the discharges from the bowels proved) were assimilated, the patient steadily lost ground, and finally died from exhaustion. The mania deepened as the case progressed, and, as already stated, the same held good as to the paralysis.

Dr. Dana, who saw the case in consultation, said the patient when seen by me was in a state of mild, restless delirium. She recognized some members of her family, but was very little conscious of her condition and surroundings; soon forgot every statement made; talked very much and incoherently. She had delusions of a rapidly shifting character, and always more or less depressing. At times she became very excited and maniacal, especially at night.

She had delusions that there were gloves upon her hands, and would constantly ask to have them pulled off. She seemed to think also that there was something upon her foot. She had paralysis of both flexors and extensors of the hands, with entire loss of grip, atrophy of the forearms, and some tenderness over the muscles.

There was also foot-drop and paralysis of the leg muscles of both limbs, more on the right. She could move the thighs, but not the toes or feet. There was considerable atrophy and tenderness; no anæsthesia could be made out in either upper or lower extremities. She evidently had paræsthesia of these extremities and some pain.

The bladder was temporarily involved, so that the patient passed water involuntarily, perhaps because of her mental condition. The rectal sphincter was normal.

It was impossible to make electrical examinations. No cutaneous trophic changes. During the time she was under my observation the paralysis and atrophy increased slightly, especially in the lower extremities. Her mental condition improved somewhat, so that she slept more and was quieter.

Diagnosis was multiple neuritis from toxæmia, and mania of multiple neuritis.

Post-mortem.—The examination included all the organs. All were found normal except the bladder and right kidney, here there was cystitis and pyelitis. The heart was *absolutely normal*. The cord was examined at four different levels, and it, together with the anterior and posterior roots, was found normal. The examination included microscopic as well as gross appearances. Unfortunately, the nerve trunks and muscles were not examined, but as the thorough nature of the examination of all other structures (the case being a supposed medico-legal one) showed no abnormality save in the bladder and right kidney, the inference drawn as to the nature of the paralysis is no doubt fair.

Remarks.—The condition was evidently that of multiple neuritis in a new association; the mania, coming on early, and prior to labor, afforded ample indications for premature labor. Two cases of multiple neuritis of simi-

[1] Read before the Practitioners' Society, April 4, 1890.

lar character are already reported—one in *The Lancet*, one in *Journal of Gynecology and Obstetrics*, Paris.

The points of interest are: 1, the multiple neuritis; 2, the heart; 3, the mania; 4, the cystitis and its extension to the right kidney.

This patient had none of the recognized causes of multiple neuritis, save that of exhaustion incident to prolonged starvation, her habits and surroundings being exceptionally good. The cystitis was evidently due to the use of the catheter in a slovenly subject.

Clinical Department.

BURIED SILK SUTURES.

By ALBERT B. HALE, M.D.,

CHICAGO, ILL.

Dr. Henry O. Marcy, in his article on "The Animal Suture" (Medical Record, March 8, 1890), questions the use of the buried silk suture, and refers to the *New York Medical Journal* of September 14, 1889, for a discussion on that point. I have had no experience in abdominal section, but I had a very interesting case in which I used a buried silk suture with no ill results, while I was acting as surgeon for the Mexican International Railroad. The patient had been struck with a crowbar by a fellow-workman, and when I found him, fifteen minutes afterward, there were all the signs of concussion, a fracture of the frontal bone, and a deep laceration involving the periosteum, muscle, and skin covering the bone. I took three sutures in the periosteum, with sterilized silk, preserved in carbolized oil, and washed in bichloride, 1 to 1,000. These I buried, and closed the superficial wound with the same silk. I am positive the silk was aseptic. The wound healed, and the visible stitches were removed on the fifth day. In ten days nothing remained but the red line of cicatrix. There had been no suppuration. Here, of course, the tissues above the bone are very thin, and any foreign body beneath ought to be perceptible; but no kind of pressure on manipulation could detect the slightest symptom of a foreign body, either to myself or to the patient; and for the three weeks I had him under observation there was every indication that the silk had been absorbed. I was so fortunate in this instance that I should not hesitate to use silk again for the same purpose.

In another case I ligated the brachial artery with aseptic silk, and have heard no report of hemorrhage or suppuration; but as the man passed out of my hands three months afterward, I cannot be positive about the result.

VERATRUM VIRIDE IN TONSILLITIS.

By A. T. HUDSON, M.D.,

STOCKTON, CAL.

There are few diseases that are so quickly recognized and understood by the average practitioner as tonsillitis. Yet it is one that is seldom arrested in its course short of suppuration. "Once having ended in suppuration, it is disposed to take the same course on subsequent occasions; so that in new attacks there is little hope of causing the disease to end in resolution" (Niemeyer). Forty years ago it was considered a triumph to help a patient through anywhere short of death.

Mrs. N——, of this city, had her first attack at the age of eighteen, while living in Massachusetts. During twenty-two years subsequently she had twenty attacks, and every one of them ended in suppuration. She says she was attended by many doctors, the best in the country.

Mr. E. N—— says he has had the disease many times, and always thought there was no cure; so when the disease was upon him he would make preparations for a siege of two weeks "lying-in," and endure the consequences. According to the best evidence attainable in favor of the ordinary methods of treatment, not more than ten per cent. recover without suppuration. It is to reverse these figures, and make ninety per cent. of cures, that I call attention to an old remedy which will do this work. Tincture of veratrum viride, given before the congestion and inflammation have progressed to molecular impairment, or within twenty-four or thirty-six hours of the beginning, will accomplish this end. The dose is four to five drops given every three hours. Often three or four doses will stop the congestion, produce sweating, and permanent relief. Morphine may be added whenever nausea occurs, before the phlogistic symptoms have yielded.

Recently, F. D——, a strong young man, who had been much exposed to rain and cold, came home at night with a sore throat and painful deglutition. This being the fifth attack he knew what was the matter, so he struggled through the night, using hot applications and other things as best he could. In the morning I gave him five drops of veratrum viride, with an eighth of a grain of morphine, every three hours. In the evening there was complete relief; and one more dose, the next morning, effected a cure by resolution. It is no assumption to say cure, in place of recovery.

It is pertinent to note that the three former times this patient had had tonsillitis, I treated him with the above plan successfully, with a term of illness not exceeding three to five days each. About a year before this last sickness was the fourth attack. Owing to my absence another physician was called. He evidently had but a slight acquaintance with the virtues of veratrum viride, and did not use it, but he worked faithfully with other things which gave the patient no relief.

The result was a painful siege of three weeks of confinement, accompanied with a fearful amount of mucus, pus, and dynamic expletives crowding out of his mouth—the old way of relief to such inward fulness. The simplicity of treatment and the promptness of relief, are ample reasons for emphasizing the value of veratrum viride in tonsillitis.

THE TREATMENT OF KELOID.

By A. G. BROWNING, M.D.,

MAYSVILLE, KY.

Referring to the above by George T. Welch, M.D., Passaic, N. J., in Record of Feb. 15, 1890, I beg to endorse it all, and to add: I have obtained even better results from hydrarg. bichlor. and collodion, than from a combination of iodine and the latter; better because I have found the cure quite as certain and more speedy. I don't think "cure" too emphatic, though aware that kelis has so long baffled knife and physic as to become the opprobrium of both. I have, however, removed only comparatively small tumors by this method, generally about the face, and troublesome only to the extent of their disfigurement, or the apprehension induced. The latter, of course on part of patients, who most times present as victims of that popular terror, "rose cancer!" "Rose," possibly, because anything so named may chance to be red; and "cancer," because it isn't known what else.

I use the bichloride in the proportion of 1 to 30 of collodion. The tumor is thickly coated with this, and allowed to remain till it exfoliates—four or five days generally. Another and another is applied in this way, till by successive coatings the growth is reduced to a level with the surrounding surface, when the cure may be regarded as complete. From three to half-a-dozen applications, owing to extent of growth, have generally proven sufficient.

In this strength little or no irritation is produced; the crust drops off, bringing with it a layer of the coagulated tissue, leaving the parts smooth and dry for the next coating. A stronger preparation—1 to 20, may be used, but

sometimes the part after its use is found quite raw. This gives rise to a sharp smarting upon the second application, but that is all; it hasn't appeared otherwise objectionable. No unpleasant symptoms have followed, and I have not yet failed in removing small tumors in this way, if persisted in, and in a shorter time than by any other known method.

The removal of these growths from the face, or localities where from friction or pressure they annoy, is a matter of expediency, chiefly. But, because they are seemingly so trifling, if for no other reason, it is something to give other than the long stereotyped reply, "physic promises nothing, and surgery but little more."

The origin of this treatment of keloid, with me, was sufficiently humble and unpretending—it took root in use of same in corns and warts! While not just congeners, I reasoned, "if so in the green, why not in the dry?"

I have found it do very well—better than anything else.

Progress of Medical Science.

The Comparative Action of the Iodides of Potassium and Sodium.—At the last meeting of the Academy of Medicine, Dr. Laborde read a very interesting note on the comparative action of the iodides of sodium and potassium. He pointed out an error now very prevalent in therapeutics—in considering isomeric substances as possessing the same physiological and therapeutical properties as their congeners. It is thus, for instance, that chlorate of potassium has been replaced by chlorate of sodium, iodide of potassium by iodide of sodium, etc. On the same grounds it was supposed that bromide of potassium might replace iodide of potassium in the treatment of syphilis, but the attempt was eminently unsuccessful. It was also thought preferable to administer chlorate of sodium in stomatitis, because it is more soluble than chlorate of potassium; whereas a more attentive examination would have shown that, while a solution of chlorate of potassium destroys in a short time false membranes, a solution of chlorate of sodium does not act on these morbid products. It was also thought that the alkaloids of the same family could be administered indifferently, those of cinchona, for example; whereas experiment shows that quinine has no action upon the nervous centres, while cinchonine and cinchonidine provoke attacks of epilepsy. It has also been proposed to administer to certain patients iodide of sodium in the place of iodide of potassium. Dr. Laborde opposed this theory, and recalled that Professor Germain Sée had long ago shown the difference of action between these two salts on the blood-pressure, which is augmented by iodide of potassium, whereas iodide of sodium scarcely modifies it. These facts were already established, and he wished to find an explanation of them. He therefore experimented on non-curarized animals, and ascertained that iodide of potassium produced general tetanus, whereas experiments with iodide of sodium, even in double quantities, produced negative results. Iodide of potassium excites the nervous centres, whence its action on the vascular system and on the heart. Dr. Laborde concluded his paper by impressing on his hearers that chemical analogies could give no just appreciation of effects on the organism, and that physiological experiment alone would enable one to establish clearly the indications for the therapeutic employment of divers drugs sometimes almost similar chemically, and yet very different from a physiological and therapeutical point of view.—Paris Cor. *Lancet.*

Segmentary Myocarditis.—At the last meeting of the Académie de Médecine, M. Robin read a paper on "Segmentary Myocarditis." This affection is anatomically characterized by the segmentary dissociation of the cardiac muscular tissue, that is to say, by the softening of the cement which unites end to end the muscular cells. What characterizes this myocarditis from the segmentary myocarditis symptomatic of valvular affections of the heart is the dissolution of the cement. No serous lesions, nor cardiac cirrhosis, nor endo-arteritis of the vessels of the myocardium are observed. The affection is mostly to be found in the aged, and in persons prematurely aged by the abuse of alcohol, or in those suffering from gout, chronic rheumatism, or some other chronic affection. In typhoid fever it may be also met with. The symptom *par excellence* of the malady is arhythmia, or want of rhythm in the pulse and the heart. Two kinds of senile pulse may be observed. In the first the arterial pulsations are neither equipotential nor equidistant, while in the second, which is by far the most important, the pulsations are very regular as to height, distance, and rhythm. Another symptom of segmentary myocarditis consists in effacement of the localized precordial shock. Auscultation reveals in all the patients weakness of the heart sounds, and irregularity of the pulse. An excellent sign which characterizes this affection from mitral insufficiency consists in the absence of tumefaction and sensibility of the liver. However, in most patients œdema of the ankles is observed. It is perhaps needless to say that patients affected with segmentary myocarditis are in a very bad general condition, and should be treated with the greatest care, for a bronchitis would rapidly prove fatal. The treatment consists in the prudent administration of digitalis and general tonics, and champagne.—*Medical Press.*

The Pre-frontal Region of the Brain.—Modern physiologists regard the pre-frontal part of the brain as the seat of character and intellect. After the removal of this part in dogs and monkeys no paralysis of any muscles or loss of sensibility occurs, but singular changes in the behavior, emotions, and character of the animals have been observed. They become livelier, restless, impatient, irritable, quarrelsome, and violent. Their movements seem purposeless, and their attention to what is going on around them and their intelligence are diminished. These observations have been confirmed by similar phenomena in the case of human beings. The well-known "Crowbar case," described by the American physician Dr. Harlow, is one in point. A young man was busy tamping a bursting-charge into a rock with a pointed iron rod, when the charge suddenly exploded and the rod entered his head under the angle of the lower jaw, came out in the frontal region, and was found some distance off, covered with blood and brain-substance. He became childish, wilful, fickle, and restless, and suffered loss of intellectual power. Gradually, however, these symptoms disappeared; he recovered and lived for thirteen years. His skull is preserved in Harvard University. —Berlin Cor. *Lancet.*

Frottement Périhépatique.—Dr. Bertrand, a naval medical officer stationed at Toulon, has called the attention of the Academy to a very valuable sign of abscess of the liver—viz., perihepatic friction sound (*frottement périhépatique*), not described in text-books (*The Lancet*). This perihepatic friction is perceived by the ear and by the hand applied to the right hypochondrium, more frequently at the level of the seventh or eighth intercostal space, on the anterior axillary line, which would appear to indicate the peritoneal origin of the lesion. This sign is the more important as it may precede by several days œdema of the part. The perihepatic friction sound is, moreover, proof that the liver is fixed to the abdominal walls by the peritoneum, knowledge which is not without importance to the surgeon. In general this friction is found at the level of the point where the maximum of pain is felt. It is also at this point where parietal œdema occurs, which would indicate the spot where any exploratory puncture should be made. The author concluded his note with the advice that, in an individual presumed to be affected with abscess of the liver, auscultation should be employed, not only over the respiratory organs, since thoracic migration of pus may have taken place, but also over the liver, to aid in diagnosing the hepatic abscess.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, May 10, 1890.

THROMBOSIS AND EMBOLISM OF THE PULMONARY ARTERY.

An article upon this subject, embodying no new cases, but containing a thoughtful review of the literature at hand, with apt illustrations of the disease, is given by Dr. Goodall in the "Transactions of the Vermont Medical Society, 1889."

As to the exact manner in which such clots are formed—whether they arise from a diseased condition of the vessel walls or from a dyscrasia of the blood; whether the primary element in the fresh clot originates from the blood-plasma or from the corpuscles immersed in it—scientific observers are still at variance, and all the more so because of the recent discovery of a new possible agent—the blood-plate. In a large proportion of cases, of course, the clotting in the pulmonary artery is secondary to a clotting in some other part of the venous system. How often it is due to the action of disease-germs and their septic products is not yet known.

A striking instance of the embolic origin of the clot in the pulmonary artery is quoted from Playfair. A lady, six months pregnant, was operated upon for anal fissure. Complete abortion occurred on the ninth day afterward, her pulse, respiration, and temperature having risen considerably during the previous twelve hours, but without any accompanying pain. At the time of abortion, and immediately afterward she experienced extreme dyspnœa, and called incessantly for air. The heart-sounds were almost inaudible, she was pulseless, and her face was very pale and anxious. Two hours later she died, with slight convulsions. At the autopsy, post-mortem clots were found in the heart, and ante-mortem clots in the pulmonary artery. In the centre of one of the latter was found a well-outlined piece of fibrin, three-fourths of an inch long, presenting at its base an irregular surface which fitted closely to a corresponding rough surface in a clot discovered in *the iliac vein*. The uterus was well contracted and quite healthy, and its veins contained no coagula.

Another case cited may be taken as an illustration of primary pulmonary thrombosis. A girl, eight and a half years of age, apparently in the enjoyment of good health, suffered one day from a slight headache. Next day she complained of a collection of phlegm in her throat, which occasionally produced vomiting of tenacious frothy mucus. She was pale, with icy feet and legs. Her eyes were sunken. There was no pulse at the wrist, the action of the heart was tumultuous, the inspirations were very deep. She complained of no pain, only of "something in the throat." At 6 P.M. on the same day she died, having been in bed only three hours. She was conscious to the end. At the autopsy the lungs were found to be congested, and the bronchi were full of mucus. There were miliary tubercles in the left lung. A thrombus was found plugging completely the pulmonary artery. None of the other organs were found to be diseased.

The history of many fatal cases renders it certain that fibrinous clots of the pulmonary arteries may exist for a long time without causing any symptoms which would lead to the suspicion of their existence, until some unusual exertion leads to a demand for more blood than can be supplied through the partly obstructed vessel, or until some extension of the clotting, or some other unfavorable complication occurs.

The prognosis is extremely grave, but it is very probable, if not certain, that such a clot in the pulmonary artery may disappear by absorption or otherwise, permitting the current to flow again in the old channel.

The treatment should be directed toward prevention of the clotting or embolism, toward support of the vital powers during the occlusion, and toward removal of the obstruction. As certain debilitated conditions of the body, with feeble circulation, seem to dispose toward thrombosis, extreme debility and great impoverishment of the blood are to be combated by the tonic and stimulant measures in common use. Especially should persons in such conditions be guarded against sudden exertion, great emotion, and other such unfavorable influences. When clots are known to have formed in the channels of peripheral veins, great care should be taken not to dislodge them and produce embolism. When occlusion of the pulmonary arteries has already occurred, the most complete rest of body and mind should be enforced and plenty of fresh air should be supplied. (Oxygen might be administered with benefit.) Carbonate of ammonia seems to be very useful as a stimulant, and perhaps as preventing further coagulation. It is doubtful whether any drug will produce absorption of the clot. This must be left to the natural powers of the body.

We might add to the above the careful use of antisepsis as a prophylactic measure, as it is probable that pulmonary thrombosis is in many cases due to the entrance of septic matter into the blood.

THE OVARIAN JUICE IN THERAPEUTICS.

In the *Archives de Physiologie Normale et Pathologique* for April, 1890, Professor Brown-Séquard continues his record of experiences with testicular juice, and adds some novel reports upon the use of injections of watery extracts of the ovaries in women. He quotes the experiments of Professor Villeneuve, of Marseilles, upon a hysterical woman, who, after a double salpingotomy continued to have crises. She was treated with injections of the ovarian juice, and cured!

Dr. Brown-Séquard adds that an American lady has been carrying on experiments with the ovarian injections with great perseverance and success. She used the ovaries of rabbits, and prepared and used the extract in the same way as was done with testicles. Experiments

were made upon more than a dozen female patients suffering from debility, insomnia, and uterine troubles. She observed return of strength, relief of insomnia, cessation of hysterical attacks, and in one old lady who had lost her singing voice, a complete return of vocal power!

It is to be regretted that the important juvenescent properties of the fresh ovaries were not known when the removal of these organs was so much in vogue in this and other cities. To have removed the ovaries, chopped them up, extracted their juice, and inoculated the patient with the dynamogenic product of her own organism would have been a superb climax of surgical and medical art.

THE SHORTCOMINGS OF SOAP.

There are probably few people who do not find the joy of living made less keen by having to read each day the advertisements of popular soaps. Their good qualities are so superlatively good, their effect on the complexion, the health, and longevity so unfailing, their chemical composition in each case so remarkably in accord with all that exact science and dermatological art could produce, that it discourages the medical man, who finds so much in his own measures that are imperfect and incomplete.

We read, therefore, with a certain sense of relief the results of an investigation made by Dr. B. H. Paul, in the *British Journal of Dermatology*, on the composition of these highly lauded toilet soaps. Dr. Paul states that for bodily ablution soaps should not contain an excess of alkali but should be neutral or nearly so. He found, however, that among toilet soaps, as usually met with, a perfectly neutral soap is the exception, and that a trustworthy soap of that kind is still a desideratum. Three of five soaps of the higher grade were described as "super-fatted" soaps, one of them being alleged to have been prepared according to Unna's formula. But in fact they all were found to contain the full proportion of alkali required for the saponification of the fat, besides some additional potash, which in one of them was considerable. It seems, therefore, that the perfect soap is yet to be made.

FIRES IN INSANE ASYLUMS.

On May 6th the Longue Pointe Insane Asylum, near Montreal, Canada, caught fire and was destroyed, with the loss of nearly fifty lives. The fire started in mid-day, but, despite this, the building was so inflammable and the means of arresting the flames so inadequate, that a great and shocking loss of life and a great many serious injuries resulted. The institution held about a thousand patients. The loss of property amounts to about $1,000,000.

The event will, of course, call forth many homilies upon the necessity of a more careful provision against fire in insane asylums. But a homily could never be more timely nor receive its impulse from a more tragic event.

In proportion to the number of insane asylums, it seems as though they were subjected to accidents from fire with peculiar frequency. Rarely does a year pass without our having to chronicle some painful accident of this kind. The fact that the insane are more or less confined in locked wards, and that they are unable to help themselves in emergencies, makes it particularly important that special pains be taken to protect them from fire.

In this country, the question has been made a prominent one only in very recent times. Dr. Kirkbride, in his work on Hospital Construction, published ten years ago, devotes but a few lines to it. His recommendations, however, were wise, so far as they went, and were evidently much in advance of those employed in the construction of this Canada asylum.

HYPNOTISM.

Hypnotism continues to be a subject of deep popular interest. One of our daily contemporaries has published a long cablegram containing an account of the hypnotic experiments of Luys and Bernheim, and others in Paris. We observe, also, that a French gentleman whose name is unknown to science has just arrived from Paris, and intends to give America the benefit of his knowledge through public and other seances. It is possible that this gentleman's arrival is more or less connected with the recent enactment in France of the law forbidding public exhibitions of hypnotism. Such a law ought to be passed in this country.

The careful and scientific study of hypnotic phenomena is deserving the attention of medical men, but much of what appears in public prints, especially that imported from Paris, is sensational and untrustworthy.

THE JOHNS HOPKINS MEDICAL COLLEGE.

The daily papers announce that an attempt is to be made to raise a fund of $200,000, to endow the Johns Hopkins Medical School. The hospital already has funds, but there is not enough to establish a college in connection with it. We are also told that this proposed school is to have a female annex, so that women shall be amply supplied with clinical opportunities.

We are much interested in the Johns Hopkins Hospital and its work. It seems, however, that if money is to be raised to endow medical schools, it would be a good plan to help on those already established. Two hundred thousand dollars would place some of the already known schools in a position to give the very best kind of instruction; but it would not go far toward starting a new school, particularly if it is to be run on a co-educational basis.

Iodoform Test for Sweet Spirit of Nitre.—The new Dutch Pharmacopœia, besides directing that sweet spirit of nitre shall be tested qualitatively with ferrous sulphate, prescribes the following quantitative test in which the formation of iodoform is made a criterion. Mix 5 c.c. of the spirit with 10 c.c. of water of ammonia, and add 2 c.c. of a solution prepared from iodine 1 part, potassium iodide 2 parts, and water 2 parts. After the black precipitate formed is dissolved, a further addition of 2 c.c. of the iodine solution should not, within half-an hour, cause the separation of crystals of iodoform.—*Medical Recorder.*

Some Physicians in Fort Wayne, Ind., are trying to afflict that town by the establishment of still another medical school there.

News of the Week.

The Kentucky State Medical Society will hold its annual meeting in Henderson, on May 14th. Dr. G. F. Lydston, of Chicago, Ill., will deliver the opening address, his subject being "Materialism *versus* Sentimentalism in the Study of Crime."

An Echo of the Haymarket Massacre.—Two physicians of Chicago have sued and recovered judgment for $457 for surgical services rendered a police officer who was struck in the thigh with a piece of a bomb thrown by the anarchists at Haymarket Square during the riots in Chicago.

The Iowa State Medical Society has had a very successful meeting in Des Moines. The following officers were elected for the ensuing year: *President*, Dr. William D. Middleton, Davenport; *First Vice-President*, Dr. J. D. McCleary, Indianola; *Second Vice-President*, Dr. J. L. Whitley, Osage; *Secretary*, Dr. C. F. Darnall, West Union; *Treasurer*, Dr. G. R. Skinner, Cedar Rapids; *Assistant Secretary*, Dr. C. S. Chase, Waterloo. The next annual meeting will be held in Waterloo.

The Pee Dee Medical Association.—On April 10th, in Darlington, S. C., the Pee Dee Medical Association held its annual meeting. Dr. C. Kollock read an interesting paper on laparotomy, and the reports of a number of cases were presented and discussed. The election of officers resulted in the re-election of the officers who served during the past year, namely: *President*, Dr. C. Kollock, Cheraw; *Vice-President*, Dr. E. Miller, Florence; and *Secretary* and *Treasurer*, Dr. J. Lunney, Darlington. The next meeting will be held in Florence, in April, 1891.

Removal of a Hospital.—The Philadelphia City Pest-House is about to be removed, as it is in the centre of a rapidly growing district, the further progress of which its presence seriously hinders. The hospital occupies fourteen and one-half acres of ground at Twenty-second Street, Huntingdon Street, and Lehigh Avenue. It was located there by a Commission appointed under an ordinance of November 24, 1862, when it was found necessary to remove the hospital from Corinthian and Fairmount Avenues. It was then thought to be so far away that the city would not reach it for nearly a century. But the march of improvement has been so rapid that in less than thirty years the building line is almost up to the hospital, and people are waiting for it to be removed in order that the property can be improved.

The Iowa State Dental Association held its annual meeting in Dubuque, on May 6th, 7th, 8th, and 9th. About one hundred members were present.

Dr. George W. Miltenberger, who recently resigned the chair of obstetrics in the University of Maryland, has been elected emeritus professor of obstetrics and honorary president of the university. Professor Miltenberger was educated at the Boisseau Academy, in Baltimore, and at the University of Virginia. In March, 1840, he graduated at the University of Maryland, and in the same year was elected demonstrator of anatomy, and has been a member of the faculty for the half century that has elapsed since that time.

The Northwest Missouri Medical Society.—At the quarterly meeting of the District Medical Society of Northwest Missouri, held at St. Joseph, in April, the following officers were elected for the coming year: *President*, Dr. James W. Heddens; *Vice-President*, Dr. F. A. McKinnon; *Recording Secretary*, Dr. Daniel Morton; *Corresponding Secretary*, Dr. W. L. Whittington; *Treasurer*, Dr. George Nash.

The National Association of Railway Surgeons held its third annual meeting in Kansas City, Mo., on May 1st, 2d, and 3d. There was a large attendance of railway surgeons from all parts of the country, and a number of important papers were presented.

Pennsylvania State Sanitary Association.—The fourth State Sanitary Convention of Pennsylvania will be held at Norristown, on Friday and Saturday, May 9th and 10th, under the auspices of the State Board of Health, acting in connection with the Board of Health of Norristown. There will be three sessions on the first day and two on the second. The annual address will be delivered on the evening of the opening day by A. Arnold Clark, member of the State Board of Health, of Michigan. Papers are expected from Hon. H. K. Weand, of Norristown, on "The Necessity for Sanitary Organization of the State under Legislative Sanction"; Dr. C. W. Chancellor, Secretary of the State Board of Health, of Maryland, on "The Purification of Drinking Water"; General D. H. Hastings, on "Some of the Sanitary Lessons of Johnstown"; Professor Pemberton Dudley, of Philadelphia, member of the State Board of Health, on "The Importance of the Early Diagnosis of Communicable Diseases and their Immediate Report to the Health Authorities"; Rev. Mr. Bridenbaugh, pastor of the Church of the Ascension, Norristown, on "The Dangers arising from Public Funerals in the Case of Contagious Diseases"; Professor Henry Leffmann, of Philadelphia, on "The Employment of Salicylic Acid as a Food Preservative"; Dr. J. D. Risley, of the University of Pennsylvania, on "The Eyes of our Public-School Children."

St. Mary's Hospital, St. Paul.—The corner-stone of the new building of this hospital was laid by Bishop James McGolrick, of Duluth, on April 20th. The building will be of brick and Kasota stone, and will be three stories in height. The architect's plans provide that ultimately this building will be only one wing of a much larger structure.

The Syms Operating Theatre.—Work was begun some time since on the excavation for the large operating theatre in the Roosevelt Hospital grounds, but was suddenly discontinued about two weeks ago. It is now ascertained that the hospital authorities began the work at their own risk before they had received the legacy of $350,000 left for the purpose by the late William J. Syms, of this city. They were assured that there would be no contest of the will, but on the day before the legal year expired a protest was filed against the will, and notice given that it would be contested. The result is, that it will be impossible to build the operating-room this summer so as to have it ready for the clinics in the fall. It is not believed that the attempt to break the will will be successful, but the contest causes, nevertheless, a most vexatious delay.

A Small Baby.—Dr. C. G. Hubbard, of Hornellsville, N. Y., reports in the *New York Medical Journal* the birth of a living child which weighed one pound and two ounces and measured ten inches in length. It lived eight hours.

The Gin Cocktail is known to have certain gladsome and refreshing qualities in those milder states of asthenia which follow a day's work and precede an evening meal. Dr. George T. Maxwell, of Jacksonville, Fla., however, in addition recommends the gin cocktail as closely approaching a specific in yellow fever. His formula is: Good gin, ℥ viij.; compound tincture of cinchona, ℥ ij.

One Result of Prince Bismarck's Retirement will, says the *British Medical Journal*, perhaps, be a notable improvement in the eyesight of his countrymen. German oculists almost unanimously attribute the extraordinary prevalence of myopia and other defects of vision in the Fatherland to the use of the national black-letter type in school-books. Prince Bismarck has always resolutely stood upon the ancient ways in this matter, and has opposed the substitution of the Roman for the Gothic character in German books. The party of typographical reform is now hopeful of succeeding in its object.

Honors to Medical Men in Italy.—Professor Paolo Mantegazza, Senator of the Kingdom of Italy, and Professor Alfonso Corradi, of Pavia, have been named Grand Officers of the Order of the Crown of Italy; and Dr. Francesco Morano, Professor of Ophthalmology in the Royal University of Naples, has been created a Knight of the same Order.

The German Congress of Internal Medicine was opened on April 15th at Vienna by Professor Nothnagel, who delivered an inaugural address before the members attending the congress, who numbered about 500. The discussion on empyema—opened by Dr. Schede, of Hamburg, who advocated resection of ribs, and continued by Dr. Immerman, of Basle, who recommended aspiration—was well sustained, and, at its conclusion, it was resolved to institute a collective investigation of the relative merits of various modes of treatment. On April 16th Professor Fürbringer, of Berlin, read a paper on "Bone Disease in Enteric Fever." Two dermatological papers followed, the first by Dr. Unna, of Hamburg, who advanced evidence to show that the universal application of oily substances to the skin tended to raise the body temperature, while gelatine preparations tended to reduce it. Professor Senator confirmed the correctness of these observations, and stated that gelatine might thus be used as an antipyretic. The second, by Dr. Mosler, of Greifswald, on pemphigus, led to an interesting discussion, in which Professors Kaposi and Weber took part. The recent epidemic of influenza was the subject of an address by Professor Bäumler, of Freiburg.

Dr. R. W. Taylor has been appointed Professor of Venereal Diseases at the Vanderbilt Clinic.

Use of the Kola-nut in Armies.—During the manœuvres of the German Army last autumn, numerous experiments were made to determine the practical utility of the kola-nut in enabling men to endure severe and prolonged physical labor. So satisfactory were the results obtained that the authorities are said to have ordered thirty tons of the drug for use in the army.

Dr. Philip Bush, of Marshall's Creek, Pa., died on May 5th, at the age of eighty years. Dr. Bush was graduated from the Jefferson Medical College in Philadelphia, in 1834, and from that time until his death, a period of fifty-six years, practised continuously in the one place.

An Invitation to California.—At the meeting of the Medical Society of the State of California, held in Los Angeles in April, it was determined to invite the American Medical Association to meet next year in San Francisco.

The Bill to Regulate Medical Practice in Maryland, which passed the Legislature, has been vetoed by the Governor.

Kansas State Medical Society.—The thirty-first annual session of the Kansas (State) Medical Society, will convene at Salina, Kansas, Tuesday May 13th, at 8 o'clock P.M., and continue in session the succeeding two days. Railroad fare will be one and one-third, on the certificate plan; reduced rates at all the hotels have been secured for the occasion. Salina is centrally located, easy of access by any of the trunk lines in the State, and it is to be hoped that the many readers of The Record in Kansas will take note of the time and place, and avail themselves of the privilege of attendance.

Dr. Charles H. May has been appointed Chief-of-clinic in Ophthalmology at the Vanderbilt Clinic, College of Physicians and Surgeons, New York.

Kentucky State Medical Society.—The Thirty-fifth Annual Session will be held at Henderson, May 14, 15 and 16, 1890.

Harlem Hospital, New York.—Dr. Edward Fridenberg has been appointed Visiting Ophthalmic Surgeon to the Harlem Hospital.

Dr. Robert W. Wescott, a well-known physician of Elizabeth, N. J., died a few days ago in Lowell, Mass. He was a graduate of the University of Pennsylvania, and was fifty-seven years of age at the time of his death. He was president of the Union County Medical Society for several years. He had been in failing health since the time of the blizzard in March, 1888, when he nearly perished from exposure.

The Union District Medical Society, composed of physicians from Rush, Fayette, and Union counties, Indiana, and Butler County, Ohio, held its annual meeting in Rushville, Ind., on April 24th. There were about sixty members in attendance.

Dr. Yung Do King, a Chinese doctor practising in this city, died recently from consumption. He was a native of Canton and had been in this country seven years, the last of which was spent in New York.

The Fair in Aid of the French Hospital in this city, which was recently closed, brought an addition of about $17,000 to the credit of the association.

Want a Swedish Doctor.—A meeting of Swedes living in Worcester, Mass., was held recently, to discuss the advisability of importing a physician of their own nationality from the other side. It was decided to write to Sweden to learn whether there are any physicians in that country willing to come to Worcester and settle.

The German Surgical Association has received the sum of $25,000 from the emperor. There are some advantages in the monarchical form of government. We see no prospect of President Harrison giving $25,000 to the American Medical Association.

The First Female Surgeon in Austria.—Medical circles in Vienna are said to be somewhat disturbed by an official order granting to a lady, who had graduated at the Berne University, the right of practising in Austria as an ophthalmic surgeon. Before this time even Austrian gentlemen who had graduated at a foreign university have been prevented from practising in Austria.

Dr. William G. Wood died at his home, in this city, May 6th, aged 77 years. He was born but two blocks away from where he died, in 1813, on his father's farm, and began his education at the old Manhattanville school. He then entered Rutgers College, at New Brunswick, N. J., and after graduation studied medicine with Dr. Stevens of this city. He began work at his profession in Harlem in 1840, and built up a very large practice. On his retirement, some twelve years ago, he was the oldest practising physician uptown.

Dr. Samuel Rush Haven, of Chicago, died suddenly at Joliet, Ill., Monday, of paralysis, at the home of his brother, the Hon. Dwight Haven. Dr. Haven was a distinguished physician and surgeon. He went to Illinois in 1834, and went out with the first troops as a Brigade Surgeon under General Grant. He was successively promoted to Division, Corps, and General Army Surgeon in the Army of the Potomac, and served on the staff of Generals Heintzelman, Hancock, and Grant. He was a native of New York State, having been born in Sheridan, Chautauqua County, in 1827.

Dr. William C. Evans, of Erie, Pa., died May 6th, at the age of sixty-one.

The Fifth Annual Dinner of the Faculty of the New York Post-Graduate Medical School took place at the Hotel Brunswick on the evening of Monday, May 5th, Dr. D. B. St. John Roosa, President of the Faculty, presiding. There was a large attendance, composed of members of the faculty and other distinguished gentlemen. The following were the toasts of the evening and their respondents: "The Medical College of New York," by Professor A. A. Smith, M.D.; "The Post-Graduate Medical School," by George Henry Fox, M.D.; "The City of New York," by Logan C. Murray, Esq.; "The Medical Press," by George F. Shrady, M.D.; "The Clergy," by Rev. Wesley R. Davis, D.D.; "The Law," by Cephas Brainerd, Esq.; and "The Medical Profession," by Professor James E. Kelly, F.R.C.S.

To Abolish Capital Punishment.—The bill to abolish capital punishment in this State was killed in the Senate, May 6th, by a vote of 7 to 2.

Onions for Insomnia.—A writer in a daily paper recommends eating raw onions before bedtime as a remedy for insomnia. Evidently he sleeps alone and by an open window.

Coroners' Juries proverbially bring in curious verdicts. The latest is by a Pennsylvania jury. An embankment caved in on some railroad laborers, and the verdict was: "Died of gravel."

Sir William Jenner has retired from practice and intends to devote himself to literary work.

The Treasurer of the Rush Monument Committee reports that so far the sum of $1,325.19 has been raised.

More Medical Colleges Wanted in Austria.—Professor Billroth thinks that Austria ought to establish a number of provincial medical colleges, so as to secure better surgeons for the smaller towns of the country. At present the Vienna School is the only one in which a thorough surgical training can be obtained.

The "Journal of the Medical College of Ohio" is the name of a new medical monthly, published in the interests of the above college, and edited by Dr. James M. French. The *Journal* follows the lines of the Johns Hopkins *Bulletin*. It makes the sixth college medical journal which has been started recently, and is doubtless the forerunner of many others. By the time that every college has its journal, and every hospital its annual report, and every society its transactions, the variety and extent of medical literature will be calculated to overwhelm the most industrious student.

The German Surgical Congress held its nineteenth annual meeting at Berlin on April 9th, 10th, and 11th. Among the topics discussed was that of ether and chloroform. Dr. Keppeter advocated the use of the latter anæsthetic. Several members, including Bruns, of Tübingen, defended the use of ether, while Bergmann declared for chloroform, and pointed out that one must not always attribute deaths that occur under anæsthesia to the anæsthetic; there were cases of death from terror before or during operations without anæsthetics. He earnestly recommended Keppeter's proposal for the collection of statistics. Thieme, of Kottbus, declared bromide of ethyl to be quite unsuitable for real narcosis. Professor Bruns discussed the subject of the treatment of tubercular joint disease. The use of iodoform was advocated, and no new facts developed. Professor Ponfick, of Breslau, read a paper on the surgery of the liver, and showed the possibility of removing large portions of it. From experiments which had been made on rabbits, it was found that the removal of the fourth part of the liver caused only a slight deterioration in the general condition. The removal of the half caused a much more serious deterioration, which, however, passed off in a few days. Even the removal of three-quarters was borne, though with very severe prostration at first. A considerable number of the animals survived this last operation, and recovered entirely. The excision of more than three-quarters of the liver did not succeed. It was found, further, that the liver had an astonishing power of repairing lost tissue. Within a few days the mutilated organ grew to more than its original size, a fact which seemed to have been known to the authors of the ancient legend of Prometheus. Professor Tillmanns showed a case of electro-puncture for aneurism of the aorta. Such an aneurism in a strong man had been completely removed by this method. The speaker used a battery of twenty elements, inserting a Stöhrer's regulator to mitigate the pain. Immediately after the introduction of the needle the aneurism sac began to shrivel, and after a series of sittings disappeared altogether. Details of other subjects discussed will be given later.

Keep on your Hat at the Grave.—A society of clergymen of Topeka, Kan., has passed resolutions opposing the custom, on the part of pall-bearers and friends, of uncovering the head at the commitment of bodies to the grave, and has requested the local medical society for their opinion on the matter. The society has unanimously endorsed the ministers' views.

The Virginia State Board of Examiners has recently issued the first license ever given in that State to a woman to practise medicine.

The Doctors Victorious.—A dispute arose recently between the contract-labor inspectors and the physicians of the Marine Hospital Service, as to which were entitled to a certain room in the Barge Office. The physicians finally obtained the room by burning sulphur in it, and thereby rendering the place undesirable from the standpoint of the inspectors.

The Revue Internationale de Bibliographie, Médicale, Pharmaceutique et Vétérinaire, is the title of a new bibliographical quarterly edited by Dr. Jules Rouvier, of Paris. It gives an indexed bibliography of current medical literature.

Not so New.—It is announced that a Berlin physician, Dr. Bröse, has devised a novel innovation in the field of electro-therapeutics, viz.—he has introduced dynamo-electricity into the office for use in the ordinary electro-therapeutical applications. This novel innovation has been in use by American physicians for four or five years.

Reviews and Notices of Books.

THE STUDENT'S SURGERY, A MULTUM IN PARVO. By FREDERICK JAMES GRANT, F.R.C.S. 12mo. pp. 817. Philadelphia: Lea Brothers & Co. 1890.

THIS compact, condensed manual is an epitome of the author's larger work on the science and art of surgery, and is adapted to the needs of the student preparing for final examination. All the essential points of a work of this kind are incorporated in the present volume, and the required information is given in a becomingly elementary form.

WOOD'S MEDICAL AND SURGICAL MONOGRAPHS. Consisting of Original Treatises and Reproductions, in English, of Books and Monographs Selected from the Latest Literature of Foreign Countries, with all Illustrations, etc. Volume V., No. 3. New York: William Wood and Co. 1890.

THIS number completes the fifth volume of this popular series of monographs on medical and surgical subjects, and yields to none of those which have preceded it in the variety and general interest of its contents; the physician and the surgeon, the student of infancy and the student of old age, the sanitarian and the neurologist, each finding something in this number to attract his attention and to instruct him. The first article is one on the "Arrest of Growth in Cancer by the Interrupted Voltaic Current" (electro-atrophy), by Dr. J. Inglis Parsons. Following this is a paper by Sir Morell Mackenzie, having the rather sensational title of "The Dreadful Revival of Leprosy." Other monographs are, "Diseases of Old Age," by Dr. A. Seidel; "Urinary Neuroses of Childhood," by Dr. Louis J. Guinon; "Varicose Veins of the Lower Extremities," by William H. Bennett, F. R. C. S.; and "The Uses of Electrolysis in Surgery," by Dr. W. E. Steavenson. The last named article is quite profusely illustrated. An index to volume V. is also contained in this number.

PRACTICAL ELECTRICITY IN MEDICINE AND SURGERY. By G. A. LIEBIG, JR., Ph.D. and GEORGE H. ROTH, M.D., etc. Philadelphia and London: F. A. Davis. 1890.

NOBODY at all acquainted with the general drift of electro-therapeutic literature during the past ten years will be likely to anticipate any radical improvement in that well-worn field, in the immediate future. The fact is that nothing short of some striking departure in electro-physics can do much for us. Such novelties as have appeared are largely technical, so that there has been practically no departure in principle for a long time. Perhaps the nearest approach to a modification of a larger sort is found in Apostoli's method of using strong electro-lytic, or, as he terms them, "chemical galvano-caustic currents."

Recognizing these things, we are not particularly surprised to find that the authors of this volume have nothing especially startling to offer us, either from their own, or the hands of others.

The first part of the book, devoted to the exposition of the laws of electrical and magnetic action, is written in an attractive manner; but we are inclined to deprecate the profuseness with which mathematical formulas are employed in the elucidation of Ohm's and Kirchhoff's generalizations. We acknowledge the difficulty of avoiding such methods of expression; we even admit their justifiableness in works on physics; but, at the same time, we are quite as positive that their presence in a purely medical book is rather a detriment than an advantage. With these trivial exceptions, the book is easy reading, the style is good, and the illustrations abundant and helpful.

THE NEUROSES OF THE GENITO-URINARY SYSTEM IN THE MALE, WITH STERILITY AND IMPOTENCE. By DR. R. ULTZMANN. Translated by GARDNER W. ALLEN, M.D., etc. Pp. 160. Philadelphia and London: F. A. Davis. 1889.

THE little work before us represents substantially a translation of two monographs by Dr. Ultzmann, who for some time past has filled the chair of Genito-urinary Diseases at the University of Vienna.

In our opinion the translator would have done well to subdivide the two long chapters of which the book is composed, as by so doing he would have enabled one to look up special points with much greater facility. As it is, we have neither a table of contents nor an index to guide us; so that there is nothing for it but to hunt about for such landmarks as the profuse paragraphing may afford. Turning from these purely technical shortcomings to the subject-matter of the book, we find that Dr. Ultzmann has performed his task with much ability, both from a theoretic and practical point of view. The descriptions of the neuroses of the genito-urinary system are good, and the classification is in the main serviceable; while the observations on pathology and therapeutics, if not specially original, are at all events sound.

MANUAL OF SKIN DISEASES, WITH SPECIAL REFERENCE TO DIAGNOSIS AND TREATMENT, FOR THE USE OF STUDENTS AND GENERAL PRACTITIONERS. By W. A. HARDAWAY, M.D., Professor of Skin Diseases in the Missouri Medical College, etc.

IN the work before us Dr. Hardaway has attempted to present a most practical handbook of skin diseases in general, and one which will be especially useful to the student as well as the practitioner, in aiding them in arriving at a correct diagnosis, and also in laying down full practical directions in therapeutics.

In part first, we find the introductory observations upon symptomatology, causes of skin diseases, diagnosis, local distribution of skin diseases, and treatment, which are given in such a clear and simple manner that, with a little careful reading, any student or physician can master the groundwork of dermatology. We are glad to see that Dr.

Hardaway does not inflict upon us, as so many do, a new classification, but wisely contents himself with the modified one of the American Dermatological Association. The various diseases of the skin are considered alphabetically, and it is to be noted that a vividly clear and terse clinical description of each disease is followed by short but graphic sections upon the general points involved, etiology and diagnosis; then follow the sections upon treatment, which are especially noticeable for their clear, simple, and practical character. By conciseness of statement, Dr. Hardaway has thus been able to present a most satisfactory summary of directions for the management of all forms of skin diseases, with a great wealth of detail. We are especially struck with the good judgment shown in each instance, of presenting the salient and generally accepted facts concerning each disease, and while not omitting most points, of keeping them in the background. We can especially commend the sections on acne, dermatitis, eczema, syphilis, and the parasitic diseases of the skin, as being particularly full in clinical description and in therapeutic detail; still all of the other and minor diseases receive full and adequate consideration.

A Text-book of Obstetrics, including the Pathology and Therapeutics of the Puerperal State. Designed for Practitioners and Students of Medicine. By Dr. F. Winckel, Professor of Gynecology and Director of the Royal Hospital for Women, Member of the Supreme Medical Council, and of the Faculty of Medicine in the University of Munich. Translated from the first German edition, with permission of the author, under the supervision of J. Clifton Edgar, A.M., M.D., Adjunct Professor of Obstetrics in the Medical Department of the University of the City of New York. 190 illustrations. Pp. xxiii–927. Philadelphia: P. Blakiston, Son & Co. 1890.

Professor Winckel is so well known to Americans, not only as a truly scientific obstetrician, but as a superior teacher, and a courteous, kindly gentleman, that we cordially welcome this excellent translation of his lectures. We already know that he is no superficial observer, and when we read that the present volume represents the results of an experience based upon twenty thousand cases, we are prepared to receive it with the respect which it deserves. It is impossible for us to enter into an elaborate analysis of the book, but a review of the table of contents will give the reader an idea of its scope. A carefully-prepared "Historical Introduction" of ten pages concludes with a list of the works on obstetrics, in all languages, which have appeared up to 1887 (when the first half of the volume passed through the printer's hands). Part I., including five sections, or twenty six chapters, deals with the physiology and management of pregnancy; Part II. (sixteen chapters), with the physiology and management of labor; Part III. (six chapters), with the physiology and management of the puerperal state; Part IV. consists of three sections, including twenty-nine chapters, devoted to the pathology and therapeutics of pregnancy; Part V. (four sections, or twenty chapters), to the pathology and therapeutics of labor; and Part VI. (four sections, or thirty chapters), to obstetric operations; Parts VII. and VIII., including twenty-nine chapters, discuss respectively the pathology and therapeutics of the puerperal state, and diseases of the new-born infant.

Each chapter is preceded by a complete list of references to the literature of the subject, which in itself is invaluable. Pathology, as may be inferred, is a special feature of the work, and represents the results of original investigation on the part of the author. The chapters on obstetric examination are especially valuable, since they show how thorough and conscientious is his method of procedure. It hardly seems, however, as if he had placed sufficient stress upon the difficulties surrounding the differential diagnosis of pregnancy. The general directions on the management of labor are replete with valuable suggestions. Their conservative tendency will be evident from this concluding sentence: "When sent for by the nurse or other person, because of some irregularity, he (the accoucheur) should not go convinced that some operation must be performed; in a word, he should have confidence in the natural forces."

The author does not believe that the diagnosis of ectopic gestation is impossible before rupture, and counsels the use of electricity before resorting to laparotomy, since the latter "is, after all, not an indifferent matter." His teaching regarding the management of abortion may not meet with general approval, at least in New York, since he maintains that "if, in an abortion or immature labor, fragments of fœtal membranes or placenta have remained behind, we are justified and obliged to proceed to operative interference only when there are severe hemorrhages from the uterus, or fever or sloughing set in." "In the absence of these indications," he adds, "I am strongly opposed to cleansing of the uterus, either by hand or instruments, because this method furnishes no guarantee against small remnants being left behind, and against direct inoculation of sanious matters into existing lesions." We cannot approve of the use of ergot, before the uterus is emptied, as he recommends.

The chapter on placenta prævia, and the paragraphs on prolapse of the cord have many practical suggestions. Part VI., which treats of obstetric operations, has an introductory chapter which, though very brief, is pregnant with common-sense. Professor Winckel believes that if the accoucheur recognizes clearly the indications, he ought never to be in doubt regarding which of the two operations should be performed. "Only one of the two is always indicated; an 'or' can never occur where there is an exact recognition of the situation." Chapters III. to VI., inclusive, on general directions, contain numerous invaluable lessons; the key-note of operatic obstetrics is contained in the sentence—"It is not always brute force which conquers!"

The chapter on extraction of the head in breech-presentations is described more clearly and comprehensively than in other text-books, and contains just those details which a student needs. The application of the forceps is carefully described, as are also the more formidable operations. The important chapter on puerperal septicæmia is clear and concise, the author concluding that "none of the processes described has any characteristic peculiar to childbed alone, and is found not only in pregnant, parturient, and lying-in women, but also in non-pregnant women, new-born children, and men." The lucid manner in which this principle is developed will do much to dispel the mystery which has been thrown around this subject by the numerous theorists who have sought to explain it, too often adding to the existing confusion.

In this hasty manner we have only sought to call attention to the salient points of this admirable work, which, though intended and especially adapted to the student, nevertheless will well repay a careful perusal by all who aspire to practise obstetrics according to the most approved modern methods. We would like to see this text-book used in this country, for the reasons that it is clear and concise, that it gives special prominence to pathology, and that every page bears evidences of that thoroughness and sound conservatism which makes its distinguished author unequalled as a teacher of obstetrics. His style is terse, but pleasing; he never aims at mere rhetorical effect. The translator deserves great credit for the manner in which he has discharged his arduous duty. The care which he has bestowed upon it shows that it was a labor of love. He has rendered the original into smooth, readable English, and the absence of foreign idioms is noticeable. We have not observed a single typographical error, which is certainly remarkable in a volume of this size. The illustrations are, with few exceptions, original, and are well executed, the type is small but clear, and the work as a whole reflects no little credit upon the well-known house from which it issued.

Essentials of Gynecology. Arranged in the form of Questions and Answers, prepared especially for Students of Medicine. By Edwin B. Cragin, M.D., Attending Gynecologist to the Roosevelt Hospital, Out-patient Department; Assistant Surgeon to the New York Cancer Hospital, etc. With fifty-eight illustrations. Pp. 192. Philadelphia: W. B. Saunders.

This handy little volume is a distinct improvement upon the ordinary student's compends, since, although extremely condensed, it is not a compilation from a few well-known text-books, but represents a judicious selection from many sources. No author who was not himself a practical gynecologist could have consulted the student's needs so intelligently as Dr. Cragin has done. We commend especially the paragraphs on diagnosis as models of brevity and comprehensiveness. Displacements and fibroid tumors of the uterus are treated at considerable length. The author has the happy faculty of describing the steps of an operation in fewer words than most gynecologists, without sacrificing either clearness or thoroughness, witness the descriptions of trachelorrhaphy, perineorrhaphy and vaginal hysterectomy.

A carefully prepared index and table of contents add to the value of the book, which we cordially commend to the practitioner, as well as to the student. Even the experienced gynecologist might well carry it in his pocket to refresh his memory in the details of his art, especially before a lecture.

On Diseases of the Rectum and Anus. By Harrison Cripps, F.R.C.S., Assistant Surgeon St. Bartholomew's Hospital. Second edition. 8vo, pp. 500. London: J. & A. Churchill. 1890.

The thorough study with which Mr. Cripps has invested his subject has been duly rewarded in the prompt appearance of a second edition. The latter has been made valuable by many alterations in the body of the text, referring more particularly to details of pathology and treatment. Especially is this noticeable in the chapters on rectal cancer and its relief by inguinal colotomy. The points on differential diagnosis are presented in an admirably clear manner and leave nothing to be desired in detail or accuracy. The various forms of adenoid growths of the rectum are also studied with great care and are accurately illustrated microscopically and in gross by a number of beautifully executed plates.

It is unnecessary to allude to the author's views regarding the treatment of those diseases of the rectum commonly met with in practice. Suffice it to say that they agree substantially with all other authorities who have had equal experience and success.

The Year Book of Treatment for 1890. 12mo, pp. 324. Philadelphia: Lea Brothers & Co. 1890.

This welcome annual is brought down in its review to September 1, 1889. It is fully equal to its predecessors, and that is saying a great deal. Among the names of the contributors we notice those of J. Mitchell Bruce, on "Cardiac Diseases;" E. Markham Skerrett, on "Respiratory Affections;" Goodhart, on "Pædiatrics" (medical); Treves, on "General Surgery;" Dr. Berry Hart, on "Gynecology;" Reginald Harrison, on "Genito-Urinary Troubles;" Malcolm Morris, on "Dermatology," etc. Valuable indexes of authors and topics are appended. W. G. Smith, of Dublin, gives a satisfactory summary of the therapeutics of the year.

Manual of Skin Diseases. By W. A. Hardaway, M.D., Professor of Skin Diseases, St. Louis Post-Graduate Medical School, etc. Pp. 434. St. Louis: Theodore F. Lange. 1890.

The dermatologists seem to have had their "innings" at manuals during the past twelve months, just as other specialists in previous years. Most of these publications are intended for those brought as students into personal contact with the authors, who disarm criticism by saying in their prefaces that they present the "matured conclusions of the best authorities," etc., and add personal views merely on a few subordinate topics and on therapeutic procedure. There is thus very little to criticise in the actual matter presented, as it is what everyone believes. We must confess, however, to a decidedly favorable impression regarding Dr. Hardaway's book. For a person beginning dermatology we could wish for nothing more plain. His description of the primary lesions, and the paragraphs on local distribution of skin diseases are especially good for beginners. An alphabetical arrangement of the various affections of the skin renders reference easy. A very definite diet table will help some readers.

A Treatise on Headache and Neuralgia, including Spinal Irritation and a Disquisition on Normal and Morbid Sleep. By J. Leonard Corning, M.D., with an Appendix: "Eye Strain a Cause of Headache." By David Webster, M.D. 8vo, pp. 259. New York: E. B. Treat. 1890.

This (second) edition of Dr. Corning's book, two years after its first appearance, shows an appreciation by the medical public of its many practical suggestions. And we presume that just in the variety and value of the latter lies the secret of its success. The author frankly disavows any intention of studying the various ills of the nervous system in a "spirit of pathological analysis," but has rather desired to directly lessen human suffering. Naturally insomnia receives special attention as being one of the most harassing symptoms of many functional nervous affections. The book is well illustrated. Dr. Webster's contribution is a concise register of considerable clinical experience in a class of cases now very common. No one can read the whole book without getting many valuable therapeutic suggestions.

A Text-book of Human Anatomy, Systematic and Topographical, including Embryology, Histology, and Morphology of Man, with special Reference to the Requirements of Practical Surgery and Medicine. By Alexander Macalister, M.A., M.D., F.R.S., F.S.A., Professor of Anatomy in the University of Cambridge. Philadelphia: P. Blakiston, Son & Co. Pp. 775. 1889.
